INDEX TO VOLUME CXLIX.

Abdominal Surgery. A new method of closing the abdomen after laparotomy, Higgins, F. A., 645; Cæsarean Section for hydatid mole, Warren, J. C., 102; Gastrotomy for foreign body, Warren, J. C., 103; Intestinal obstruction following operation for appendicitis, 104; Laparotomy for intestinal obstruction, Beach, H. H. A., 104; the operative treatment of umbilical hernia, Warren, J. C., 400.

Addresses. Surgical tuberculosis 1, Burrell, H. L.; the Shattuck Lecture, Smith, T., 57, 87, 115, 139; memorial meeting to John Homans, M. D., 389; Bradford, E. H., 397; Cabot, A. T., 393; Richardson, M. H., 389; Shattuck, Geo. B.; address at memorial meeting to Morrill Wyman, M. D., 195; Walcott, H. P., 195; Nichols, J. T. G., 203; Councilman, W. T., 202; Fitz, R. H., 201; the relation of laboratory research to the general practitioner of medicine, 473; present problems, an address to the nurses of the Lakeside Hospital, 521.

Adrenalin in surgical shock.

Advice. Lay advice to recent graduates in medicine, 27; American Journal of Orthopedic Surgery, 301; American Society of Clinical Surgery, 536; American research, 411; athletics for girls, 534; baby incubator, 245; Behring on tuberculosis, 525; Boston Association for the Relief and Control of Tuberculosis, 50; British Medical Association, 244; cholera, 357.

Albuminuric Retinitis, 649.

Alcohol. Treatment of alcoholic toxemia, Hall, Arthur J., 350; studies on the action in disease, Cabot, R. C., 93; alcohol versus alcoholics, Buckingham, E. M., 137.

Altitude Treatment for Tuberculosis. Hall, J. N., M. D., 350.

American Research, 411.

Anatomy. Problems of clinical, Dwight, T., 119.

Anesthesia. Scopolamin-morphin mixture in labor, 180.

Antityphoid. The protection effect of antityphoid inoculation, 470.

Aphasia. As a complication of measles, Gilman, Warren R., 177.

Appendicitis. Intestinal parasites in, 623.

Appendicostomy, 25.

Arnold, H. D. The relation of laboratory research to the general practitioner of medicine, 473.

Association of military surgeons of the United States, 182.

Austin, A. E. Indol of the feces as a measure of putrefactive processes in the intestines, 672.

Baginsky, Adolf. Typhoid fever in children, 721.

Baldwin, L. B. Syphilis in dentistry, 159.

Bartol, J. W. Influence of wind on phthisis, 237.

Beach, H. H. A. Memorial to Wm. Cadge, 557.

Bibliography. Albert, E., diagnosis of surgical diseases, 685; Schamberg, J. F., compend of diseases of the skin, 686; Holmes, B., surgical emergencies, 686; Mason, R. D., office treatment of rectal diseases, 686; Moynihan, B. G. A., surgical treatment of gastric and duodenal ulcers, 686; Stevens, A. A., modern matera medica and therapeutics, 685; Hale, H. E., anatomy, medical epitome series, 714; Cowles, Edward, M.D., retirement of Dr. Edward Cowles from the McLean Hospital, 690; Drew, C. A., was he insane? a study in mental diagnosis, 674; centenarian, 689; Farlow, J. W., some cases of facial erysipelas from erosions of the nasal septum, 670; Egberts, S., manual of hygiene and sanitation, 657; Lea Bros. & Co., medical news visiting list, 657; Muller, P. J., das Schulzimmer, 657; Ogden, J. B., clinical examination of the urine, and urinary diagnosis, 656; Stoney, Emily, practical points in nursing, for nurses in private practice, 656; Taylor, J. J., physicians pocket account book, 657; Wood & Co., Wm., medical record visiting list, 657; Baruch, S., the principles and practice of hydrotherapy, 657; Abt, J. A., practical medicine series of year books, vol. 7, pediatrics and orthopedics, 685; Allingham, H. W., operative surgery, 685; Atwater, W. O., Billings, J. S., Bowditch, H. P., Chittendon, R. H., and Webb, W. H., physiological aspects of the liquor problem, 326; Baldwin, L. B., and Larned, E. R., syphilis in dentistry, 159; Barton, W. M. and Wells, W. A., a thesaurus of medical words and phrases, 466; Bridge, N., tuberculosis, 353; Chart of the three great systems — arterial, venous and nervous, 524; Clark, J. J., protozoa and disease, 604; Cohen, S. S., a system of physiologic therapeutics, vol. 10 pneumotherapy by Tissler, P. L., 159; Cohen, S. S., a system of physiologic therapeutics, vol. 8 rest mental therapeutics, suggestion by F. X. Dercum, 410; Crandall, F. M., how to sleep well, 466; Cross, M. I., and Cole, M. J., modern microscopy — a handbook for beginners and students, 631; Dorland, W. A. N., the American illustrated medical dictionary, 466; Dwight, E. W., Dwight's epitome of medical jurisprudence, 308; Eisendrath, D. N., a textbook of clinical anatomy, 493; Gould, Geo. M., the American year book of medicine and surgery for 1903, 159; Grunwald, L., atlas and epitome of diseases of the mouth, 20; Hammer, W. J., radium and other radio-active substances — palonium, actinium and thorium — with a consideration of phosphorescent and fluorescent substances, the properties and applications of selenium, and the treatment of disease by the ultra-violet light, 576; Helferich, H., atlas and epitome of traumatic fractures and dislocations, 21; Hunn, J., handbook of climatology, 381; Jacobi, Prof., portfolio of dermochromes, English adaptation of text by J. J. Pringle, 524; journal of proceedings of the sixth annual convention of the national association of state, dairy and food departments held at Portland, Ore., 409; Matthews, J. McDowell, how to succeed in the practice of medicine, 604; Minot, C. S., a laboratory text-book of embryology, 493; Muir, R., and Ritchie, J., manual of bacteriology, 21; Mumford, J. G., a narration of medicine in America, 551; Opie, E. P., disease of the pancreas — its cause and nature, 189; Pawlow, J. P., the work of the digestive glands, 576; Peterson, R., obstetrics, vol. 5, in practical medicine series of year-books 108; Peterson, F., and Haines, W. S., a textbook of legal medicine and toxicology, 270; Phillips, R. J., spectacles and eye-glasses, 381; Pilgrim, M. F., mechanical vibrator stimulation — its theory and application in the treatment of disease, 189; prevention of disease, translated by Bulstrode, H. T., 137; Pusey, W. A., and Caldwell, E. W., the practical application of the Röntgen rays in therapeutics and diagnosis, 575; Raymond, E. et Janet P., les obsessions et la psychasthénie, 139; Richards, Geo. L., nose and throat work for the general practitioner, 575; Robinson, Beverley, essays on clinical medicine, 551; Robinson, D. H., the Latin grammar of pharmacy and medicine, 631; Rockwell, A. D., the medical and surgical uses of electricity, 189; Suter, Wm. N., a manual of refraction and motility, 353; Schäfer, E. A., the essentials of histology, 159; Scheube, B., the diseases of warm countries, a hand-book for medical men, 270; Spalthalz, von W., Handatlas du Anatomie des Menschen, 381; Szymonowicz, L., a text-book of histology and microscopic anatomy of the human body, including microscopic technique, 189; Toldt, C., and Rosa, A. D., an atlas of human anatomy for students and physicians, 576; Warden, A. A., an English hand-book to the Paris medical school, 326; Yeo, I. B., a manual of medical treatment of clinical therapeutics, 551.

Bitters, The physiology of bitters, British Medical Journal, 581.

Bitzer, L. The case of Louis Bitzer, Lane, E. B., 728.

Blake, J. B. Preliminary report on five cases of renal decapsulation, 171.

Blake, J. B. and J. H. McCollom. General peritonitis complicating scarlet fever, 639.

Blood Pressure. Some observations on, in the insane, 422.

Boards of Health. Report of New York tenement house department, 718; sanitary supervision of public water supplies a protection to public health, 687; sanitary conferences for the health officials of Connecticut, 717.

Boards of Health. Conference of the state and provincial boards of health of North America, 637; oppostion to Manila board of health, 355; work of New York tenement house department, 498.

Bonney, S. G. Internal medicine, to what extent required, or elective in the medical course, 507.

Boston Dispensary, 468.

Bovine Tuberculosis. Unclean milk and bovine tuberculosis and the tuberculin test, their relation to the public health, 894, 563.

Bowen, J. T. Scabies and impetigo contagiosa, 529; report on dermatology, 73; methods of teaching dermatology, 296.

Bradford, E. H. Address at memorial to John Homans, M. D., 397; the resistance of tissues as a factor in the manual reduction of congenital hip dislocation, 249.

Bradycardia, 331.

Brain. A brain hardened by Kaiserling's method, showing the track of a bullet, Whitney, W. F., 730.

Brain Tumor, 575.

Brent, Bishop. Work in the Philippines, 162.

Briggs, J. B. A note on the association of a rise in systolic blood pressure with the onset of perforative peritonitis in typhoid fever, 343.

Bright's Disease. Remarks on surgical treatment of chronic Bright's disease by renal decapsulation, Guiteras, R., 520.

Buckingham, E. M. Alcohol versus alcoholics, 137.

Bullet Wounds. Bullet wound of chest, 373.

Burns, Frod'k S. Some observations on X-ray therapeutics in skin disease, 481.

Burrell, H. L. Surgical tuberculosis, 1.

Burrell, H. L. and Cushing, H. W. Report of cases from the surgical service of the Children's Hospital, 372; report on progress of surgery, 431; Report on progress of surgery, the value of enterostomy in selected cases of peritonitis, 461.

Cabot, A. T. A case of calculus anuria relieved by operation, 465; address at memorial meeting to John Homans, 393; nursing as a profession, 193; observations on the effect of cathetic drainage on the function of the kidneys in interstitial nephritis and pyelonephritis, 559; acute flexion of the gall bladder as a cause of biliary colic. Its relief by operation, 725.

Cabot, R. C. Studies on the action of alcohol in disease, especially upon the circulation, 93.

Calculi. The formation of biliary calculi elsewhere than in the gall bladder, 715.

Calvert, W. J. Record of parasitic infections in the Philippines, 484.

Cardio-Pulmonary Murmur. The clinical associations and significance, Putnam, J. J., 8.

Carcinoma. Carcinoma of choroid metastatic from prostrate, Greenwood, A., 286; Surgical aspect of cancer of the intestines, Gage, Horne, 277.

Carcinoma. Adeno-carcinoma of rectum, 485; the English cancer research fund, 218.

Carcinosis. Case of carcinosis with secondary nodule in the eye, Southard, E. E., 287; a case of carcinosis of eye, 287; Gastric cancer, 292.

Catarrh. Chronic catarrh of the middle ear, 153.

Chapin C. S. Minor surgery in country practice, 310.

Charcot Joints, 71.

Chase, H. L. Efforts to abate the mosquito nuisance in Brookline, 123.

Cheever, D. W. Privileged medical communications, 259; advantages of small doses of opium, 247.

Chemistry, Physiological. Vejux-Tyrode, M, 14

Chloroform. Investigation on the action of chloroform, 160; Danvers Insane Hospital, 659.

Cholera. Prevalence of cholera in Manila, 54.

Chute, A. L. Urethral tuberculosis with report of a case, 361

Circulatory System. Perirenal hemorrhage, 32; measurements of blood pressure, 97; blood pressure after alcohol, 94; studies on the action of alcohol in disease, especially upon the circulation, Cabot, R. C., 93.

Clark, J. F. Nasal polypi, 147 cases, 10.

Climatology. Report of meeting of American Climatological Association, 682, 711.

Climatology. The invalid's Egypt, 221.

Clinical Department. Report of cases from the surgical service of the Children's Hospital, 372; a case of sarcoma of the lower jaw, 695; a case of post-typhoidal myositis of the rectus abdominis, 599; a case of myxedema, 567; report of meeting of the staff Mass. General Hospital, 428, 458, 485; mirror writing 515; two unusual forms of fracture,—fracture of the capitellum; fracture of the fifth metatarsal by inversion, 734.
Codman, E. A. Report of three cases of traumatic rupture of the kidney, 201; the formation of loose cartilages in the knee joint, 427.
Coley, Wm. B. Results of one thousand operations for the radical cure of inguinal and femoral hernia performed between 1891 and 1902, 17.
Color. The need of lantern test, Williams, C. H., 121.
Columbia University. Changes in the medical department, 81.
Cook, P. H. A case of epilepsy and nephritis simulating puerperal eclampsia, 568.
Cotton, F. J. and O'Neil, R. F. Routine treatment in a genito-urinary clinic; functions of such a clinic, 538.
Councilman, W. T. Address at memorial to Morrill Wyman, 209.
Craig, D. H. The relation existing between respiratory and intrapelvic disease, 281.
Cumston, C. G. Historical notes on the law governing civil malpractice in the ancient times and middle ages, 699.
Cumston, C. G. The plague of Athens, 449.
Cunningham, J. H. A table for operations upon the kidney through the lumbar incision, 597; a new frame for the treatment of fractures, 732.
Cushing, H. W. and Burrell, H. L. Report of cases from the surgical service of the Children's Hospital, 372; progress of surgery, 431–461.

Death. What was the cause of death? Paine, A. E., 731.
Delano, S. As to Pope Leo's case, pleuro-pneumonia, 652.
Dermatology. Report on, 73: Roentgen Rays in dermatology, 321; report of American Association, 296–321; scabies and impetigo contagiosa, 520.
Diagnosing. Pleuro-pneumonia, 652.
Diet. The dietary treatment of constipation, 314.
Diet. Consumption of horse-meat as food, 354; Daily Medical Journal, 191; Harvard Medical Alumni Association, 26.
Digestive System. Adeno-carcinoma of the rectum, Porter, C. A., 485; acute pancreatitis, operation, recovery, Porter, C. A., 430; case of post-typhoidal myositis of the rectus abdominis, Scannell, D. D., 599; cancer of the intestine, etc., its surgical aspect with report of cases, Gage, H. 277; dietary treatment of constipation, Hewes, H. F., 314; echinococcus cysts of the liver and lungs, Stone, A. K., 363; recent progress in gastro-intestinal diseases, Joslin, E. P., 292; gastric tetany, Moynihan, B. G. A., 501; inferences to be drawn from the examination of the gastic contents, Joslin, E. P., 232; intestinal obstruction from a twist and a tightly constricting band, Beach, H. A., 104; intestinal obstruction following operation for appendicitis, 104; intestinal parasites in appendicitis, Hubbard, J. C., 623; medical treatment of gastric ulcer, Wilbur, H. G., 208; obstruction of intestine, 429; the pathology and treatment of tardy post-operative intestinal obstruction with report of cases, Elliot, E., 47; report of case of gangrene of fifteen inches of cecum and ileum after operation for appendicitis; relief by artificial anus after repeated operations, Dandridge, N. P., 18; stomachal and intestinal derangements and affections of the fauces, pharynx, and air passages, Robinson, B., 535; study of pathological fermentation in the stomach, Hewes, H. F., 504; surgical treatment of gastric ulcer, Munro, J. C., 203; unclean milk, 563; vegetable food in gout and nephritis, 570; vesico-intestinal fistula, Hubbard, J. C., 402.
Dislocation. Cervical and its reduction, 445.
Dorland, W. A. N. American pocket medical dictionary, 657.
Drew, C. A. Was he insane? A study in mental diagnosis, 640.
Dudley, A. W. Septic endocarditis, 13.
Dunton, W. R. Some observations upon blood pressure in the insane, 422.
Durm, C. H. Observations on iodine reaction in children, 511.
Dwight, Thomas. Problems of clinical anatomy, 119.

Eclampsia. Renal decapsulation for puerperal eclampsia, 434.
Edes, R. T. Address at memorial to John Homans, M.D., 390.
Editorials. Preliminary training of nurses, 221; mortality of tenement-house population, 223; appendicostomy, 25; scientific work in psychiatry, 49; Boston Association for the relief and control of tuberculosis, 50; the regeneration of spinal nerve roots, 51; signed editorials, 80; Manila death rate, 80; changes in the medical department of Columbia University, 81; medical legislation of 1903, 109; paratyphoid fever, 110; suppression of the news of suicides, 111; obesity in youth, 133; nursing as a profession, 133; Journal of the U. S. Army Medical Corps, 134; investigations on the action of chloroform, 160; municipal hospital for tuberculosis, 161; prevention of tuberculosis, 162; Bishop Brent's work in the Philippines, 162; spotted fever, 190; a daily medical journal, 191; legislation against the toy pistol, 191; progress in the treatment of the dependent poor, 216; etiology of yellow fever, 216; the diagnosis of insanity at sight, 217; Dr. Morrill Wyman, 218; hydrophobia, 243; the British Medical Association, 244; the pathology of smallpox, 245; sanitary administration in Pennsylvania, 271; the invalid's Egypt, 272; the late Major Walter Reed, M.D., 272; the new Massachusetts General Hospital —out-patient department, 273; the Long Island hospital investigation, 299; as others see us, 300; American Journal of Orthopedic Surgery, 301; alleviation of tuberculosis, 327; an epidemic of typhoid fever under peculiar circumstances, 327; department store pharmacy, 328; sex in industry, 328; the opening of the schools, 354; the consumption of horse-meat as food, 354; opposition to Manila board of health, 355; mortality statistics, 356; Stokes-Adams disease, 382; the water supply of New York, 383; opium trade in the Philippines, 383; eye-strain, 384; typhoid fever and impure ice, 410; international congresses on school health, 411; American research, 411; overcrowding of the profession, 438; the inoculation of a chimpanzee with syphilis, 439; new out-patient department Mass. General Hospital, 439; eye-strain, an over-worked theory, 466; the legal status of faith-healing, 467; the Boston Dispensary, 468; report of the surgeon-general of the army, 494; a year's medical book production, 495; Dowie in New York, 495; the therapeutic possibilities of radium, 524; Behring on tuberculosis, 525; American Society of Clinical Surgery, 526; physicians liability insurance, 552; athletics for girls, 554; the Nobel prizes, 554; euthanasia, 555; the master word in medicine, 577; the Spreckels physiological laboratory, 577; the organism of smallpox, 578; the German emperor, 578; public health problems, 605; the title of surgeon, 606; a timely rebuke, 606; scientific study of old age, 632; regeneration of the spinal cord, 633; a multiplicity of congresses and exhibits on tuberculosis, 633; Danvers Insane Hospital, 659; some reports upon food inspection, 658; report of the Surgeon-General of the United States Navy, 716; formation of biliary calculi elsewhere than in the gall bladder, 715; the retirement of Dr. Edward Cowles, 716; Harvard oarsmen, 688; scarlet fever, 687; sanitary supervision of public water supplies a protection to public health, 687; the cancer question, 743; hydrotherapy and allied methods of treatment, 744; investigation of the Butler typhoid epidemic, 743; physicians for the Philippines, 743.
Egypt. The Invalid's Egypt, Morrill, F. G., 221.
Emerson, Wm. R. F. Diseases of house officers in hospitals, 590.
Endocarditis. Malignant, Miller, L. C., 38; Endocarditis, septic, Dudley, A. W., 13.
Epidemics. The epidemic nature of appendicitis, 461; epidemic of diphtheria on shipboard, 185; the Ithaca epidemic, 548; epidemiology of typhoid fever, 548; epidemic of typhoid at Butler, Pa., 634; epidemic of typhoid fever under peculiar circumstances, 327.
Epididymitis. Acute epididymitis in an undescended testicle with gonococci, demonstrated in the excised organ, Murphy, F. T., 36.
Erysipelas. Cases of facial erysipelas from erosions of the nasal septum, Farlow, J. W., 670.
Esophagus. Brief summary of the surgery of the esophagus, Mixter, S. J., 288.
Euthanasia. 497.
Eye. Hitherto undescribed membrane of the eye and its significance, Verhoeff, F. H., 456; case of carcinosis with secondary nodule in the eye, Southard, E. E., 287; eye strain, 384.
Eye Strain. An overworked theory, 442; euthanasia, 555.

Faith Healing. A legal decision, 469.
Fever. Scarlet fever. General peritonitis complicating, McCollom, J. H. and Blake, J. B., 639; spotted fever, 190; epidemic of typhoid at Butler, Pa., 634; the Ithica epidemic, Covill, L., 548; the management and treatment of typhoid fever, LeFevre, E., 547; history, cause, and mode of transmission of yellow fever, 186; typhoid fever and impure ice, 410; etiology of yellow fever, 216.
Fevers. Scarlet fever, 687.
Fistula. Vescio-intestinal fistula, Hubbard, J. C., 404.
Fitz, R. H. Address at memorial to Morrill Wyman, 201.
Foster, F. P. Surgical advance in the United States, 663.
Food. Some reports upon food inspection, 658.
Football. English opinion of football, 635.
Foster, F. P. Surgical advance in the United States, 663.

Gage, Homer. Cancer of the intestine, etc., its surgical aspect with report of cases, 277.
Gall Bladder. Acute flexion of the gall bladder as a cause of biliary colic. Its relief by operation, Cabot, A. F., 795.
Gall Stones. Gall stone disease, 462.
Gastric Contents. Examination of, Joslin, E. P., 232.
Gastric Ulcer. Surgical treatment, Munro, J. C., 203; diagnosis of gastric cancer, Joslin, E. P., 292; medical treatment, Wilbur, H. G., 208; gastric tetany, Moynihan, B. G. A., 501; German emperor, 579.
Gilman, W. R. Report of a case of aphasia as a complication of measles, 177.
Gland. Present status of surgery of the prostate gland, Thorndike, Paul, 167.
Goldthwait, J. E. Tuberculosis of the spine, a statistical study of the cases in the orthopedic department of the Carney Hospital, 342.

Address.

SURGICAL TUBERCULOSIS.

BY HERBERT L. BURRELL, M.D., BOSTON.

(Concluded from No. 26, page 692.)

HOSPITALS.

HOSPITALS have not, as a rule, recognized the necessity for providing for the out-door treatment of tuberculosis. Dr. F. Rufenacht[27] states that "in several of the general hospitals and infirmaries in England, such as St. Thomas' Hospital in London, the North Staffordshire Infirmary at Stoke upon Trent, the Sheffield Royal Infirmary, etc., consumptive patients have been treated with more or less success by open-air methods. In the new infirmary for Camberwell the top story in each wing is to be set apart for the open-air treatment of consumptives, and is to have nearly all its wall space occupied by windows."

Burdett[28] states that "the Bethany Hospital in Berlin has had broad balconies added to the wards, where many of the patients are kept in bed, not only in the daytime, but at night." He gives plans and descriptions of the new University Hospital at Halle, which has wide verandas on the south side of the four surgical wards only, the windows being casements, opening down to the floor, so that a bed can be rolled or carried out. He states that the new hospital at Saint-Denis also has verandas on the south side of the wards. The story of the doctors who kept their patients out on the balcony until nine o'clock at night, and finally tried leaving them out all night, at the Bethanien Hospital in Berlin, is interesting. They were entirely convinced by practical experience, by patients sleeping out of doors, of the benefit of this treatment.

OUT-DOOR TREATMENT OF TUBERCULOSIS.

All of the foregoing leads me to believe that the necessity for out-door treatment of surgical tuberculosis is not sufficiently well recognized by general surgeons.

The improvement that occurs in tuberculous nodes of the neck, without operation, has for years attracted my attention, and in many instances where an operation was inexpedient I have advised the patient to live and sleep out of doors. In the majority of these cases there has been marked improvement, and in some cases apparently permanent recovery.

One of the first instances that attracted my attention to the importance of the out-door treatment of surgical tuberculosis was a patient upon whom I had operated for tuberculous peritonitis. The patient, a woman, aged thirty-eight, had a typical condition of the peritoneal cavity. She was operated upon, a large amount of fluid was removed, the peritoneal cavity was drained for a fortnight, and the abdominal wound then healed; yet for months the patient did not improve in the way we expect following an operation for tuberculosis of the peritoneum. During the summer she lived in a tent, and from the time that she lived and slept out of doors her improvement was very marked. During the summer she gained eighteen pounds, all evidence of tuberculosis disappeared, and three years later she was apparently in perfect health. At the time this occurred I considered that her improvement was simply a delayed one following operation.

A most striking instance of improvement occurred three years ago. A man, thirty-seven years of age, who was married, came to me for tuberculous epididymitis. The vas deferens on the affected side was corded and knotty. A careful examination of the urine was made, and tubercle bacilli were eventually found. Naturally an unfavorable prognosis seemed inevitable. An operation was done, and the tuberculous testis and cord were removed. After waiting three or four weeks, the patient having cystitis with tenesmus, a suprapubic cystotomy was done. Two small tuberculous areas, one the size of the little finger-nail, were found at the base of the bladder. Suprapubic drainage was established, and I finally advised the patient to go to his home and make himself as comfortable as possible, as a fatal ending was more than probable. The patient was of more than ordinary intelligence, and, turning to me, asked if there were nothing else that could be done in the way of general treatment for the disease. He himself suggested to me that if people with pulmonary tuberculosis weree benfited by living out of doors, he might be made better by living and sleeping out of doors. I, of course, acquiesced, and he had a tent constructed on his lawn and slept there from April 15 until into December — out of doors practically every night during the summer. He gained during this time thirty-four pounds, or from 118 pounds to 152 pounds. At the end of three years apparently the tuberculous process has been arrested, he is engaged in his ordinary occupation, that of a book-keeper, and I believe his life has been saved, not by my operation, but by a recognition of the value of out-door treatment of tuberculosis.

In spite of the warnings and protests of experts in the treatment of pulmonary tuberculosis, two errors with regard to the out-door treatment of pulmonary tuberculosis remain deep-rooted and widespread in the profession. The first is the sending of patients in advanced stages of tuberculosis to sanatoriums. The second is the failure to recognize the need of absolute rest, literally sitting still out of doors all day long, on every day, so long as there is evidence that the tuberculous process is still active.

Trudeau has intelligently insisted upon the need of absolute rest during the active period of tuberculosis.

The natural cure of tuberculous areas, it seems to me, demands three things: (1) Physiological rest to the part; (2) pure air and sunlight; (3) ample nutrition to the tissues to check the progress of the process. At the best, the tuberculous area in a lung must "throw out of commission" that part of the lung for the time being. There are not many principles in medicine or surgery, but if there is one in which I thoroughly believe, it is that of physiological rest,[29] and this principle is just as applicable to the treatment of pulmonary tubercu-

[27] London Zeit. for Tuberculose, 1901, p. 297.
[28] Hospitals and Asylums of the World, vol. iv, p. 60.
[29] Hilton's Rest and Pain.

losis as it is to the treatment of a tuberculous area in the hip- or knee-joint.

TENT TREATMENT.

Occasionally, here and there, within the past few years have appeared suggestions as to the out-door treatment of surgical tuberculosis. Dr. H. P. H. Galloway in 1902,[30] before the American Orthopedic Association, brought forward and advocated strongly the use of tents for the treatment of tuberculous joint-disease (Fig. X). Dr. Galloway claims that while out-door life is of great assistance

FIG. X. — Tents used by Dr. H. P. H. Galloway, at the Toronto Orthopedic Hospital.

in the treatment of all tuberculous bone and joint affections, it is particularly useful in that class of patients whose recuperative power seems to have been exhausted and are being slowly worn out by discharging sinuses which other means of treatment have failed to heal. He does not claim that tents offer the best solution of the problem of securing the nearest approach to continuous out-door life, but that properly designed tents suitably located are much better than the average hospital ward, and that they are an efficient and inexpensive supplement to the regular wards. He thinks that with private patients an effort should be made to secure the benefit of sunshine and fresh air, when for any reason residence in a sanatorium is impracticable or undesirable. Many patients who have a lawn in connection with their homes can be induced to fit up a private tent and occupy it even during the winter months.

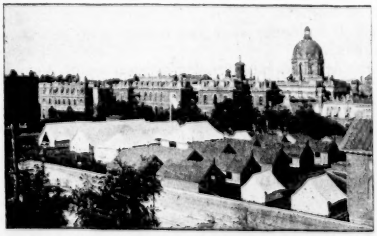

FIG. XI. — Tent wards at the Boston City Hospital.

For many years the Boston City Hospital, under the administration of Dr. Rowe, has had a tent service in summer, in which, at times, surgical patients have been treated. The advantages of this service have been very marked. Figs. XI and XII show

FIG. XII. — Interior of a tent ward at the Boston City Hospital.

the perspective of this outdoor camp and an interior view of one of the tent wards.

The means to gain this outdoor life for patients are many. An excellent type of tent is described by A. Mansfield Holmes. Figs. XIII, XIV and XV show the construction of the tent pavilion.

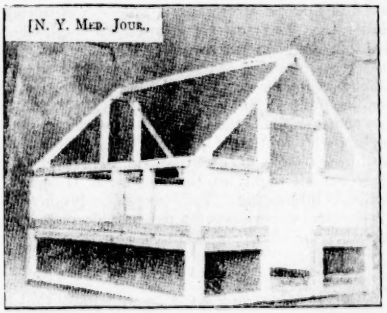

FIG. XIII. — Frame of "tent cottage," wainscoting in position. The inner wall of heavy canvas is in position on the front and rear end and the right side. The two-inch opening above the wainscoting is clearly shown.

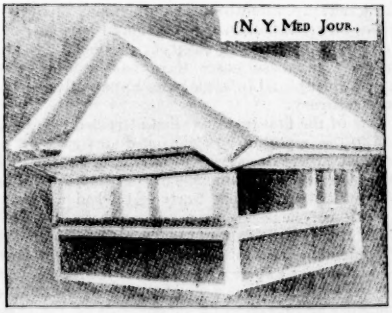

FIG. XIV. — "Tent cottage" as used in summer. The upper sections of the outer walls are converted into awnings. The rear end shows the inner wall intact. Side shows the upper half of the inner wall lowered, which practically removes the side of the "tent cottage," converting it into a "tent-pavilion." When thus converted the sun can penetrate to any portion of the interior.

[30] The General Management and Constitutional Treatment of Tuberculosis of Bones and Joints. Special ref. to Use of Tents.

The approximate cost of constructing these tent cottages is $60.

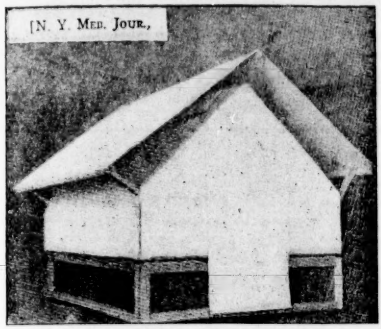

FIG. XV. — The "tent cottage" as used in winter; the fly intact, the sides and door closed, the "roof window" open. The opening between the two sections of the outer wall is plainly shown.

HOME TREATMENT.

Dr. Millet, of East Bridgewater, has recognized the necessity for caring for his patients by out-door life, and his article on "The Night-Air of New England in the Treatment of Consumption"[31] is extremely suggestive and very valuable. Dr. Millet has been good enough to let me have illustrations of the "shacks" that he has had built for the treatment of tuberculous patients (Figs. XVI and XVII), also of the balconies or verandas where

FIGS. XVI AND XVII. — Two of Dr. Millet's "shacks." Note the extreme simplicity and consequent cheapness of construction.

patients sleep, that have been "built out" in connection with many cottages. Figs. XVIII, XIX, XX, XXI and XXII are balconies built out from buildings in Brockton and Bridgewater, and here

FIG. XVIII. — Sleeping balcony.

the patients sleep, from May until November or December, only the rainy nights driving them in.

FIG. XIX. — Roof used as a sleeping balcony.

The improvement in these cases, I am told by Dr. Millet, is very great indeed.

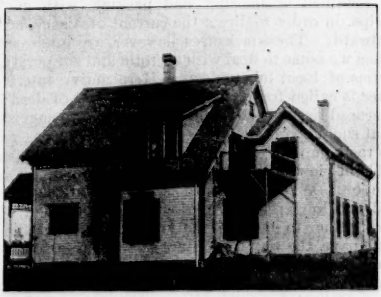

FIG. XX. — Sleeping balcony.

The public are quite aware of the benefits of out-of-door treatment, and Phil May has expressed in

[31] Md. Med. Journ., January, 1900.

Punch, March 4, 1903, the length to which this fad may be carried (Fig. XXIII).

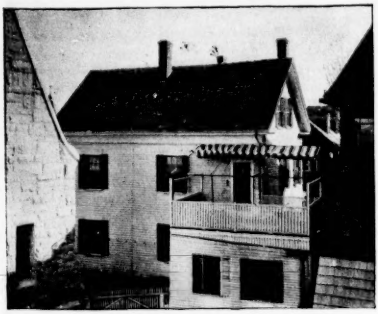

FIG. XXI. — More pretentious sleeping balcony.

A. A. Babrow[32] believes that surgical or local tuberculosis is simply a manifestation of a general infection and may be grouped under two forms, showing certain dissimilarities in their course; the one is a chronic process characterized by infiltration and formation of new connective tissue; the other is also chronic at times, though oftener subacute, and consists in a cellular infiltration which forms tubercles and through their necrosis leads to cheesy degeneration. In either instance the advent of pus cocci transforms the sluggish process into an acute inflammation. In the absence of a specific remedy our therapeutic efforts must aim at increasing the patient's resisting powers, thus aiding him to overcome the microbic invaders. All hope of salvation by removing the diseased part is distinctly illusory, since surgical tuberculosis must be considered as the local manifestation of a general infection. We combat the chronic non-suppurating variety with local rest and counter-irritating measures, like hot applications, iodin or the cautery, which all act beneficially by attracting leucocytes and phagocytes to the affected tissues, as well as by stimulating the local circulation. A similar result is obtained by incising and packing with gauze strips, in order to direct the current of tissue fluids outward. These measures, however, are inadequate when we come to deal with necrotic and suppurating forms of local tuberculosis. Here active interference is called for, and operative removal of dead or diseased tissue is advisable. It is to be recognized that such operations are merely palliative measures, as the complete removal of affected areas is impossible in view of the persistent general source of infection. When this truth is recognized, surgeons will no longer be so anxious to operate, but will seek rather to increase the strength of the patient and pave the way for nature's own cure. In this connection climatic influences deserve all recognition. Prolonged stay (one to one and one-half years) at the seashore exerts a marked salutory effect, especially in the case of children; the sea air, the bathing and, not least, the sunlight, contribute their respective share to the final result. Solar rays play a highly important rôle in the treatment of local tuberculosis, and patients should be instructed to expose the diseased parts to the sunlight.

[32] Russki Vratch, Jan. 18, 1903.

EFFECTS OF SUNLIGHT AND ELECTRIC LIGHT.

In connection with the exposure of wounds to sunlight, it is interesting to consider the use of the Finsen light. Dr. Valdemar Bie,[33] who is associated with Finsen at Copenhagen, as his assistant, states that Finsen has discovered that sunlight or arc electric light produces a widening of the skin capillaries which may last for five or six months.

FIG. XXII.

(*Overheard during one of our recent stormy days.*) "What cheer, matey! Doin' any business?"

"Garn! Wot yer gettin' at? I ain't 'ere to do business. I'm takin' the hopen hair treatment!" — *Punch.*

"Finsen has demonstrated a widening of the capillaries of the skin which lasts for a long time, as a result of light. Finsen exposed the skin of his arm to an electric arc light; upon the arm were various glass plates and also two letters of the alphabet drawn with India ink; where these covered the skin, the skin retained its white color; the lighted part of the skin, on the contrary, became red, swollen and later pigmented. After a period of four months the skin was still so pigmented that the white areas were still visible where the glass plates had been; but after five or six months the entire skin was white. If one now rubbed the skin, the marks again became visible, in that the portions of the skin which had been covered with the glass plates did not become so red as the surrounding skin. The dilatation of the vessels of the skin which results from exposure to light can, therefore, last five to six months."

[33] Light Therapy. Deutsche Aerzt. Ztg., Berl., 1902, Aug. 15, ii, pp. 361-5.

The effect upon the capillaries is only produced where the ultra-violet rays strike the skin. Light produces a stimulating effect upon all the lower animals, and Finsen has proven this upon the embryos of salamanders and upon worms. He has also shown that the stimulating influence is due to the actinic rays. These rays penetrate cartilage and skin, but are absorbed by the blood. This was interestingly proven by Finsen, who found that by rendering the ear bloodless the light would pass through the cartilage and would not pass through the ear when it was filled with blood. The ultra-violet rays have ten times as much bactericidal power as all the rest of the spectrum taken together, but they have very little power of passing through the skin. The chemical rays of light do not reach the deeper parts of the body at all, or at most in a very limited degree. The literature on the use of Finsen's rays is becoming very interesting, and one of the best articles is that called "Phototherapy," by Prof. Niels R. Finsen, Copenhagen, "translated by James H. Sequeira, M.D., Lond., M.R.C.P., 1901. There can be little doubt but that the use of Finsen's rays is of definite value in certain cases. Its exact value and limitations have not been determined, but the use of sunlight, it is clear, has been demonstrated from time immemorial. Professor Poucet allows the sunlight to fall upon a diseased joint two or three hours daily, and Milliez has written a thesis an this subject. Poucet states: "I cannot criticise the results that Milliez describes as good; but a direct influence upon the tubercle bacilli in this way is not possible; it is hardly to be denied that the nourishment of the limb may possibly be improved by the rich blood supply which results from the light bath."

Robinson[34] states that the importance of sunlight in tuberculosis patients is becoming more and more generally recognized. Abrams[35] has done some interesting experimentation on the penetrability of the solar rays. He finds that a dry skin is very resistant to the penetration of the solar rays; that the penetrability of the skin is increased by using lanolin externally and subcutaneous injections of distilled water. A very interesting experiment was done, which should be verified. Subcutaneous inoculations with a virulent culture growth of tubercle bacilli were made upon rabbits The animals were then subjected to the action of the solar rays concentrated at the point of inoculation on ten consecutive days. No tuberculous process resulted, while in other rabbits similarly inoculated, but not subjected to sun, there resulted tubercles (in which tubercle bacilli were found).

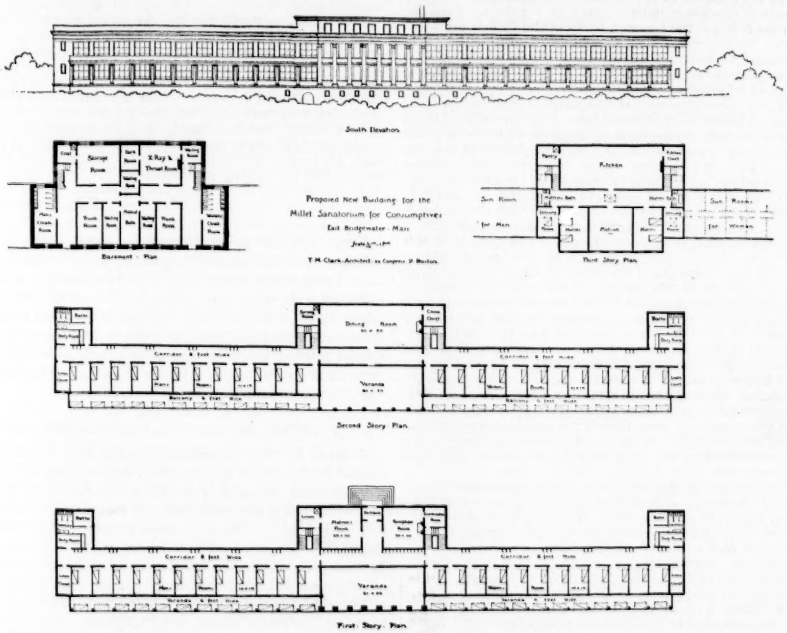

FIG. XXIII.

"Other experiments were conducted to determine whether the solar rays in greater concentration could be employed by interposing colored glass, which, in a measure, excluded the heat rays and allowed unimpeded passage to the chemic rays. The result was an unequivocal demonstration of the fact that when such media were interposed it was always at the expense of the actinic action on soliopaper." Abrams has used the solar ray in the treatment of a tuberculous ulcer of leg which had

[34] Phila. Med. Journ., 1899, iii, pp. 54-6.
[35] Ibid, 1899, i, pp. 175-8.

resisted the conventional treatment, including rest and curetting, for over a year. The ulcer healed in less than three weeks under treatment with the solar rays. He has also used solar rays quite extensively in aborting furuncles and in the treatment of cervical lymph noditis of presumable tuberculous origin.

My colleague, Dr. F. S. Watson, has written me a letter, of which the following is an abstract. The letter shows clearly that the out-of-door treatment of surgical tuberculosis is not properly recognized.

DEAR DR. BURRELL: It is a remarkable fact that, with the constantly present object lesson afforded by the results of climatic and hygienic treatment of pulmonary tuberculosis, when properly and conscientiously carried out, as it is in the best sanatoriums and elsewhere in the hands of some experts individually, so little effort should have been made to apply the same principles to those forms of disease usually classed as surgical. That this is true is indicated by such facts as the following: —

(1) No paper has been presented before the American Surgical Association urging the adoption of that method of treatment for surgical cases, whether in conjunction with or without surgical treatment.

(2) Physicians connected with sanatoriums for the treatment of tuberculous disease, and those practicing in the health resorts frequented by persons with phthisis, see but very few patients having surgical forms of the malady. This is illustrated by an inquiry recently undertaken by the writer as to the results of the climatic treatment in that class of cases, in the course of which he addressed a circular letter to every member of the American Climatological Association, which almost all of them were kind enough to answer. The questions were put with regard to tuberculosis of the genito-urinary organs only, and asked the personal experience of those gentlemen as to the results of its climatic treatment. There were just four out of the whole number who did not say that they had no experience in the care of such cases. Of the four, there was one who had had twelve patients of the sort, and the other three reported their observations with regard to from one to four cases, and had not seen more than that number. Some years ago a similar request for information was sent to twenty representative general practitioners, and none of them had knowledge of more than three cases at the most, and there were but two or three patients whose history was known definitely for long enough periods to give them any value.

The replies of the members of the American Climatological Association furnished the following information with regard to sixteen cases: In five there was complete arrest of the disease. Seven showed great improvement, but still had evidence of the disease. Two were not improved. Two died.

The reply of Dr. Henry Loomis is of interest, though it does not supply details. He says, "A number of cases have been sent to the Loomis Sanatorium by genito-urinary specialists for climatic treatment. The results have surprised everybody" in their favorable character. He refers specifically to one case considered as hopelessly ill by Dr. Keyes, who sent him for that form of treatment, in which the patient was "perfectly well at the end of a year."

It is not necessary to quote from the other letters. I will refer briefly to six cases under my own observation for periods of eighteen years in the longest to ten years in the shortest, in which the patients, though not having been under systematic climatic treatment, have all led out-door lives and been in very favorable conditions. Three of them were subjects of renal and three of testicular tuberculosis. In all there has apparently been an entire arrest of the process. In one the disease began in the testes and the seminal vesicles were invaded. Here it has remained without further extension for five years, the patient being in robust health all the while.

This year at the meeting of the American Association of Genito-Urinary Surgeons in Washington, one of the best and most experienced observers among the surgeons of this country, Dr. Chismore of San Francisco, made the first definite and strong plea that has been presented to the Association for a more extended trial of climatic treatment for cases of genito-urinary tuberculosis, as opposed to the surgical treatment.

We are fairly familiar with the results of surgical treatment of some forms of tuberculosis, notably those in which the disease is seated in the bones, which is the most favorable form of tuberculosis which comes under the surgeon's care, and those which involve the genito-urinary tract, in some of which the radical surgical treatment is far from encouraging, to say the least, — nephrectomy for renal tuberculosis, for example, despite the few brilliant successes that have attended it.

What we lack is knowledge of what can be accomplished by the climatic and hygienic treatment of these cases, either in conjunction with surgical treatment or without it, according to circumstances. We can get no information from general practitioners, specialists or surgeons, for they none of them have had any important experience in the matter, nor shall we have this knowledge supplied until sanatoriums for the treatment of surgical tuberculosis, or else special provision in the present ones, is made for the reception of such cases, and are put in the hands of competent surgeons. The medical specialists do not feel competent to assume the care of cases of a surgical character, therefore surgeons cannot send such cases as need surgical care as well as climatic treatment to resorts which are appropriate otherwise. There are signs of awakening interest, however, in this matter and it is fairly safe to predict that the pendulum will begin to swing in that direction before long, go to the inevitable too great extreme and then settle down to its proper excursion.

Very truly yours,
F. S. WATSON.

From the foregoing it may be seen that orthopedists and occasionally genito-urinary surgeons have recognized that surgical tuberculosis requires something besides operation. The treatment of tuberculous areas should include not alone active operative measures, when necessary, but the surgeon should always consider the expediency of exposing them to the sun's rays. General surgeons have not recognized its importance.

DEFECTS OF HOSPITAL CONSTRUCTION.

A ward for the treatment of surgical tuberculosis should have as its prime essentials a maximum of sunlight and the ability to move the beds out on a veranda, where the patients may sleep, if expedient, day and night. It is perfectly obvious that it is impracticable to construct a hospital at practically $1,000 per bed for the treatment of such a universal scourge as tuberculosis, and I now wish to speak of some of the defects that I believe exist in modern hospitals. The failure to recognize that a hospital must have the maximum of air and light is lamentable.

Recently I had occasion to visit a modern hospital which had been constructed by eminent architects in one of the most intelligent communities in New England. It seemed to me defective in many points. The hospital was beautifully situated, but it was winged forwards at the east and west so that much of the south sunlight was shut off. Many of the administration rooms of the hospital were on the south side, which should be devoted entirely to wards and bedrooms. The best part of the hospital building, the top, was occupied by a laundry. The most central part of the buildings, where there is the maximum of sunlight, was used as a reception room for visitors. The doors were smooth and made of jointed boards, but the butts projected. The

angles and corners of the room were rounded off, but it would require hours each day for a diligent housemaid to clean the carved mantels. The windows were not flush with the wall but were dust-traps. In one small room the best sunlight was excluded by a tree. The conventional shade, lace curtains and picture-molding existed in many of the rooms, but the beds were provided with an aseptic, smooth, painted, steel temperature chart. The windows in the building were small and of such a height that if opened slightly at the bottom the wind would blow directly upon the beds. The walls were not built of hollow brick, and already the water of condensation was forming on the walls. The operating room was elaborately fitted with a chandelier directly over the operating table, so arranged that the dust could be readily shaken into an open abdominal cavity. There were gratings over the ventilating shafts instead of cheese cloth. Expensive foot water-taps, which were complex in construction, afforded lodgment for dirt. The wall area in one ward had about one fifth of the total possible window space. There were no piazzas. Convalescent patients could be placed on a roof garden which was reached by a ladder. The kitchen was in the northwest top corner of the hospital and the ward maids had the most sunny rooms in the hospital. The engineer of the building slept in a room in the cellar, with a 2 x 4 window. The operating room had tiled floor, glazed brick and a marble dado, but the steam pipes were so close to the wall that the room could not be mechanically cleaned.

This construction is going on at the present time in many of our modern hospitals; and it is very natural that it should occur. The Board of Managers tell their superintendent that they want a building to cost a certain amount of money; they employ the best architect they know, a man who may or may not have made a study of hospital construction. The architect and the superintendent of the hospital are placed practically in charge. Rarely is the staff of the hospital more than allowed to look at the plans of the building. The architect naturally turns to the superintendent as the one representing the Board of Managers, and what the superintendent wishes is put into effect. Superintendents of hospitals, as a class, are not aware of the advances that are being made in medicine, and of the necessity for air and sunlight in the wards of a hospital. They feel and believe that a monumental structure is necessary, but in consequence of their environment and isolated position, so far as the medical profession is concerned, they do not realize that a new order of hospital construction is or will be imperative. The economies of hospital construction have never, so far as I know, been deliberately studied as have those, for example, of mill construction.

If the state is to deal with the great problem of controlling an almost universal scourge, tuberculosis, a more economical construction of hospital buildings is imperative. This can be done only by architects who are willing and anxious to meet the demand of a minimum cost of construction combined with superintendents who are familiar with, and appreciate the necessity for, the maximum amount of air and sunlight in their buildings.

Prof. T. M. Clark, architect, of Boston, has given me the plans for the building of a proposed sanatorium for Dr. Millet of Brockton, Mass. (Fig. XXIV). I find that he has carefully considered the essentials in construction of a hospital for tuberculosis: (1) He has made provision for the maximum of sunlight and air. (2) He has arranged the rooms so that a bed may be wheeled out of doors on a piazza or balcony. (3) He has provided a sun parlor at the top of the building. (4) He has studied the economy of construction. We should recognize that all the south side of a hospital should be devoted entirely to the treatment of patients, and that the north side should be reserved for hospital administration.

Conclusions. — The prime essentials for the treatment of tuberculosis are physiological rest, outdoor treatment and ample nutrition to the patient. Whether the tuberculous area is in the lung, in a joint, in a lymph node or in the intestines is a detail. Where it is possible, the tuberculous area should be excised, especially if it threatens to invade vital structures; combined with the removal of the tuberculous foci, patients should be treated by physiological rest, fresh air and sunlight. The excision of a small area from the hip-joint, while it may give a brilliant immediate surgical result as to first intention and a cure, mutilates the patient. On the other hand, by the recognition of physiological rest and outdoor treatment, such patients may be efficiently treated, and life and limb saved.

In the modern construction of hospitals we do not sufficiently recognize the necessity for a maximum of sunlight and air; provision is not made to allow patients in their beds to be moved out on to verandas, that they may be in the air and properly protected.

There is perhaps no community that is so well supplied with cottage hospitals as New England, and yet how little are they used for the outdoor treatment of tuberculous patients!

If the physicians and surgeons of the cottage hospitals in New England will utilize their hospitals for the treatment of tuberculous patients, on the lines of physiological rest and outdoor treatment, and will do less major surgery, — for example, brain tumors, — they will do more good in the community than they do at present. The health of this Commonwealth is largely in the hands of the members of this society, and if I can impress upon you the necessity, in dealing with this problem of tuberculosis, first to advocate the establishment of an adequate number of sanatoriums for the treatment of tuberculosis, either by the State, cities or towns, a step will have been taken towards its control. Again, as members of the Massachusetts Medical Society, you should recognize that it is not necessary that your patients suffering from tuberculosis should be sent far from their homes, but that by erecting bed platforms, as Dr. Millet has done at the patients' homes, they may be satisfactorily treated in their own homes. The work which is being carried out by Dr. Bowditch at the Sharon Sanatorium is worthy of the highest commendation, but that is for a specially selected class of patients. The work which is done at Rutland must command our admiration, but it is to you, as the practitioners of this Commonwealth, who visit from time to time the homes of the people, that I turn and beg that

you will consider the necessity, in tuberculosis both medical and surgical, of treating patients by physiological rest, and giving them the maximum of air and sunlight.

THE CLINICAL ASSOCIATIONS AND SIGNIFICANCE OF THE CARDIO-PULMONARY MURMUR.[1]

BY JAMES J. PUTNAM, M.D., BOSTON.

THE cardio-pulmonary murmur has been regarded by most physicians as of somewhat accidental occurrence, indicating perhaps some unusual relationship of the heart and lungs, and almost certainly due to compression or aspiration of a piece of lung by the contracting heart, but as of no clinical significance except in so far as it was liable to be mistaken for a sign of valvular lesion. Such was my own supposition until — a good many years ago — I became impressed with the relative frequency of its occurrence among certain classes of patients, namely, young and middle-aged male neuropathics and asthenics, who were often spare in build, long-chested, and usually with rather weak muscular systems and (I should now add) elastic chest walls. Subsequent investigations have fully confirmed this impression, while, meantime, the finding of corroborative statements published by various other observers has increased my confidence in its substantial correctness. When anything is said at all, by those who have written upon the subject, about the general nutrition and characteristics of the persons among whom this murmur has been found, some such description as that just indicated is usually given, or — as is often the case — it is noted that the patient has signs of pulmonary tuberculosis.

For the past two or three years I have paid closer attention to this clinical relationship between the cardio-pulmonary murmur and the neuropathic and asthenic tendencies, and offer my experience thereon in a preliminary form, together with certain other facts which may help to broaden our conception of the possible significance of the sign.

Potain, who, after Laennec, was the pioneer in the clinical study of these sounds, groups together as cardio-pulmonary or exo-cardial, all the so-called "functional" heart murmurs, including those usually classed as hemic. Recent studies[2] have, however, made it clear that this is an incorrect classification, and that the major part of the "functional" murmurs are due to defective co-ordination, defective action, impaired nutrition and relaxation of the cardiac muscles and of the arterial walls.

The cardio-pulmonary murmurs are of different origin, and yet they, too, are heard pre-eminently under some of the conditions which favor the occurrence of the "muscular relaxation" sounds, namely, during disturbed innervation. Not infrequently they disappear during the course of a somewhat prolonged examination.

They are not especially characteristic of acute anemia and the excessive fatigue following athletic exercise,[3] but they are temporarily accentuated by the nervous excitement attending an examination of the heart, as in the case of the men offering themselves as candidates for positions on the police force.[4] Both sorts of murmurs may disappear before the examination is over and it is, indeed, not certain that it is always possible to distinguish between them, though the fact that the cardio-pulmonary sound ceases at the end of a forced expiration is probably decisive under ordinary circumstances. There is, however, another relationship of the cardio-pulmonary murmur which is of especial interest, namely, that to the interrupted or cog-wheel respiration, or "heart-breath," that form of respiration, namely, where the inspiratory sound, instead of being continuous, is rhythmically broken by accentuated puffs corresponding with the contractions of the heart.

Although it is true that tubercular consolidation favors the conduction and perhaps the occurrence of these respiratory sounds, yet careful physiological studies have shown that the phenomenon is, in its main features, to be detected under normal conditions, and these studies acquire a special interest when it is admitted that there can be no radical difference between the interrupted respiration and the cardio-pulmonary murmur. Both sounds are due to displacement of air through the heart's action or the blood-current, and both are heard, not infrequently, on the same subject. When this is the case, it is my experience that to the ear (or stethoscope) placed near the apex or over the body of the heart it is the cardiac element which makes the strongest impression, while at the base, or, as sometimes, in the axillary line, the sound which is heard is of such a kind that one is no longer tempted to classify it as a cardiac murmur at all, but as an interrupted inspiration. Yet the differences must be of degree, essentially or alone.

The physiological studies which have been alluded to as establishing the fact that the respiration of normal individuals is modified, directly or indirectly, by the heart's action, have been discussed by Dr. S. J. Meltzer, and the conclusion reached by him, partly on the basis of original experiments, is in favor of the view that this effect is due, not to the changes in size and position of the heart itself, but to displacement of air attending the propulsion of blood through and out of the chest. Under ordinary conditions the amount of influence exerted on the respiration in this way is but very slight, but I presume there can be no doubt that the "cog-wheel" respiration (or one form of it if there be more than one) is only an exaggeration of this (normal) phenomenon which is discoverable by careful tests.

Although the rules given by Potain and others doubtless serve, generally, to distinguish the cardio-pulmonary murmur, yet, inasmuch as there is not one of them that is not violated, there seems to be some question whether it is always possible to differentiate the cardio-pulmonary murmur with positiveness from that which has been called neuro-muscular, and I am free to admit that in my own

[1] Presented by title at the eighteenth annual meeting of the Association of American Physicians, May 14, 1903.

[2] As those of Prince, Stengel and Arnold in this country.

past observations I may have failed, in a few cases, to differentiate between them with sufficient care. It is, indeed, not very uncommon to find a transient murmur of very slight intensity, heard at or near the apex, especially, I think, in men, which disappears before one has the opportunity to fully satisfy himself as to its nature. After allowing for errors of these sorts, however, I feel justified in the statement that the true cardio-pulmonary murmur is very rarely to be detected among vigorous persons of either sex, even where such persons are temporarily ill with what might be called asthenic diseases. On the other hand, it occurs with relative frequency among markedly neuropathic and asthenic males, but again, not nearly so often among females, even when neurotic and poorly nourished. This is especially striking in view of the fact that the murmur of the left base, which is so very common among feeble and anemic women, is very rare among feeble men.

In order to ascertain approximately the actual and relative frequency of the cardio-pulmonary murmur, I have looked over the records of 400 private patients whom I have examined during the year and a half since the beginning of 1902; one half of the 400 cases have been classified in general terms as neurasthenic or neuropathic, and the other half as ill with disorders of other sorts.

The cardio-pulmonary murmur was heard in about 30 of these 400 cases, there being of course a few that were doubtful. Of these 30 cases, at least 26 belonged in the neurasthenic group, and only 4 in the non-neurasthenic. Even as regards these there was some question as to the group in which they should be placed. As regards sex, 26 of the 30 patients were men and 4 women. These figures recall a tabulation by Matthews,[5] of Providence, R. I., who reports 32 patients, of whom 23 were men and 9 women, though saying, at the same time, "I am not aware that sex has any influence in the production of this sound." On the other hand, Squire, of London, reported 23 cases in 1898, of which 13 were the cases of men and 10 of women. Fourteen of these patients, however, 9 men and 5 women, had pulmonary tuberculosis.

As a check to my own observations I have recently asked several gentlemen who have occasion to examine large numbers of patients in the out-patient department of the Massachusetts General Hospital to listen to this murmur with especial care, and their investigations confirm my own. In the men's room the cardio-pulmonary murmur is of rare occurrence — at least in a pronounced form; not more than three or four examples having been found in the examination of four hundred or more persons. In the women's room it is somewhat more common, perhaps occurring in 2% of the cases. In the neurological department, however, in the special class of patients to which I have referred, namely, the pronounced neuropathic and asthenics, it has been found in 8 or 10%.

As regards the diagnostic characters of the cardio-pulmonary murmur, I can corroborate the statements of those who have noted its occasional presence as well during the diastole as during the systole of the heart, and the fact that it may be heard in the axillary line and even at the back. On the other hand, I cannot find that the murmur depends to any obvious extent upon the rapidity or turbulence of the heart's action, or that it is at all necessarily influenced by changes in the position of the patient. Further studies may correct this view.

The fact that the murmur is made to disappear by forced expiration has been repeatedly made use of as affording a hint as to its origin. The difficulty in the way of explaining this expiratory disappearance seems to me, however, to be considerable, and to be still greater when regarded in the light of another fact which I have observed, namely, that a similar disappearance can sometimes be brought about by the strong compression of the chest wall by an assistant while auscultation is going on. Furthermore, it is noteworthy that after being banished through the procedure the murmur does not always return at once, or perhaps even during the remainder of the examination.

The fact, now abundantly substantiated, that the cardio-pulmonary murmur, if not heard exclusively among neuropathic, constitutional asthenics and tuberculous patients, is heard far oftener in them than in any others, still demands an explanation. If this is found it may throw much light upon the origin of the sign. In fact, the patients belonging to these groups present several interesting peculiarities which may be more or less important in this connection.

In the first place, the heart muscles in these cases are liable to be weak, their innervation defective and the beat tumultuous, irregular, rapid or of changing rhythm. In the next place, the chest wall may be unduly yielding, more or less collapsed from early rickets or other nutritive disorders or otherwise deformed. The thorax has, indeed, been repeatedly noted as unusually long, and slenderly provided with muscles. Finally, the lung may contain tuberculous deposits or cavities, or may be abnormally placed with relation to the heart. On the other hand, there is no single one of these peculiarities which is universally present. The neuropathic patients do not always have deformed or feeble chests; the poorly nourished persons are not always markedly neurasthenic or neuropathic. Again, it must be admitted that the cardio-pulmonary murmur itself is not heard with such frequency, even among that class of patients who have it relatively often, as to imply a necessary concomitance with any particular signs or symptoms of other sorts.

There is, however, one possible way of regarding the sign under discussion which clothes it with special interest, and at the same time makes the task of explaining its genesis slightly easier. The cardio-pulmonary murmur may, namely, be classed with the numerous peculiarities or stigmata which are met with so often among neuropathic persons, and yet neither always present nor always implying, of necessity, a neuropathic constitution.

If the ranging of this murmur under such a head as this does not yield a true account of its pathogenesis, it does provide a new point of departure for which an explanation may be sought.

The researches of later years have shown, with increasing clearness, that it is not only alone in connection with such toxic affections as myxedema that changes of bodily type, of definite form, occur. There are many other tendencies as well which are

[5] Prov. Med. Journ., 1901. II, 116-121.

as far reaching if not so serious in their action. The stigmata of constitutional neurasthenia are multiple, and within certain limits fairly constant; and they include such different states as nutritive disorders of the skin and its appendages, abnormalities in the formation of the thorax, prolapse of the abdominal viscera and, on the other hand, a great variety of peculiarities of the life and functions of the nervous system. It is only to a few of the abnormalities that I wish to call attention in this connection, and these are the changes in the thorax, the enteroptosis of Glenard and the vasomotor disorders; or, in general, the disorders of innervation of the heart and blood vessels.

It is in just the class of cases which I have described as particularly liable to the cardio-pulmonary murmur, namely, among the slender, rather feeble neurasthenics, that the tendency to ptosis of the abdominal viscera is pre-eminently found, but more commonly in women than in men. Stiller, who has had a large experience in abdominal examinations, discussed this point some years ago, and pointed out at the same time another stigma of neurasthenia to which this same group of persons is also liable, namely, a relatively loose attachment of the tenth rib of the right side to the thoracic cage. I have found the cardio-pulmonary murmur to be present in connection with both of these signs, though the association is by no means invariable or necessary. It will be remembered in this connection that it is the right kidney which is especially liable to prolapse. The innervation of the heart and arterial system is peculiarly apt to be affected in neurasthenics. Thus, Erben [6] finds that slowing of the pulse to the extent of three to six beats is apt to be brought on by bending over once or twice or by throwing the head backwards, and this change is but slowly recovered from. Again, irregularity and rapid beating of the heart are easily brought on by efforts of various sorts. In view of such facts as these, it has seemed to me not impossible that among the causes for the cardio-pulmonary murmur it might be reasonable to think of some abnormality or defect of the innervation by which the action of the heart is brought into relation with that of the lung. It can hardly be doubted that some such mechanism as this exists, for we know that at every expiration and every inspiration the conditions of the cardiac circulation are altered, and it would be a strange anomaly indeed if this change failed to be registered and regulated through the action of the nervous system. Surely a purely mechanical explanation of the cardio-pulmonary murmur is inadequate. For why should an overlying piece of lung be aspirated or compressed by the passage of the blood through the chest of a nervous and feeble person, and not by that of a vigorous and healthy man? The task of explanation becomes much easier if we may assume that the regulatory mechanism governing the tension of the lung, or the tension of the vessels, has been damaged, or that the relation between the two has become defective. One may imagine, for example, some such disturbance to exist as is seen when a swinging pendulum receives a knock which imparts to it a twisting movement, that only gradually passes away. Similarly, perhaps, under the influence of excitement, the co-ordination of the respiration and the heart's action or the vascular tension may become disturbed, and yet be restored by the compression of the chest or the action of forced expiration. I do not pretend that even this explanation is an adequate one, but only that it may serve as the prototype of some other which is really satisfactory.

NASAL POLYPI: A STUDY OF ONE HUNDRED AND FORTY-SEVEN CASES.

BY J. PAYSON CLARK, M.D., BOSTON.

ALTHOUGH the existence of nasal polypi was recognized early in the history of medicine, and although more has probably been written about them than about any other affection of the nasal chambers, our knowledge of them is still, in many respects, far from satisfactory. What are the immediate causes of the growth of nasal polypi? What are the predisposing causes? Can all cases be permanently cured, or only certain varieties? Such are some of the questions which continue to puzzle many of us, and to no one of which would any single answer be universally acceptable or satisfactory. It was with the hope of eventually being able to throw a little light on one or more of these unsettled questions that I began, about seven years ago, to get as complete a history and keep as perfect a record as possible of all the cases of nasal polypi which came under my observation. This I kept up with occasional interruptions but with more or less regularity for several years, during which time I collected the records which form the basis for

[1] Read (by title) before the American Laryngological Association May 14, 1903.

this paper. In order to have the histories as uniform as possible, and not omit any point that might be of importance, I had cards printed, giving brief headings, indicating the various questions to be asked and the symptoms and appearances to be observed, leaving space for a description of the treatment and subsequent history. Although I had taken, as I thought, a good deal of pains in the preparation of these cards, I found, as time went on, that they might have been improved upon in a number of ways in their general arrangement, and that I had omitted some questions which might have been of value, such as the question of previous injury to the nose and the condition of the lower turbinates. As to the two items mentioned, records were obtained in many of the cases but not as a routine. In presenting the result of this clinical experience I shall not advance any new theories, but simply add the support of such evidence as I have been able to collect to statements already made by others, or show where this evidence does not support them.

The greatest hindrance which I experienced in making a study of these cases and noting the result of treatment was the difficulty of sufficiently impressing upon patients the importance of following up treatment and reporting as often as desired for observation. In spite of strict injunctions to the contrary, the majority of patients in my experience cease coming as soon as their nasal respiration is free, and only appear when their noses are again occluded. Strange to say, this statement seems to apply in a great many cases to those who also have a purulent discharge from some sinus as well as to those who have only vasomotor symptoms. The nasal discharge is disregarded if the nose is clear.

PATHOLOGY.

This portion of the subject has been so thoroughly presented by such able observers as Jonathan Wright, Hopmann, Chiari, Hajek, Swain, John McKenzie and others, that I shall pass it over with only a brief statement, which I believe nobody will now dispute, namely, that true myxomatous tissue never occurs in nasal polypi, which must, as a rule, be considered histologically as stretched and edematous mucous membrane. To quote from Wright: "While the amount of fibrous tissue varies between *nil* and a condition which might well be given the name of fibroma, the vast majority of polyps consist simply of the normal amount of loose areolar tissue infiltrated and stretched with serous exudate." As to the site of these growths, Zuckerkandl's researches have shown that the usual situation is in the region of the middle turbinated bone, from some portion of the outer wall of the nose concealed by the middle turbinate, but more commonly from the turbinate itself, either from the lower border or from the outer or (more rarely) the inner surface. In all of my cases the site of the polyps is recorded as being "on the middle turbinate," "under the middle turbinate," "in the region of the middle turbinate," and in a few cases "above the middle turbinate." In several cases I have a note of polyps visible only in the posterior nares, and having their origin distinctly above the middle turbinate. Of 146 cases, 107 had polypi in both nostrils, 19 in the left and 20 in the right only. Seventeen cases in which the polypi were in one nostril only were seen last by me over five years after they had been conscious of unilateral obstruction, and in not one of them was there the slightest evidence of polypoid degeneration of the mucous membrane in the other nostril. This experience leads me to believe that it is not as rare an exception as Bosworth states for these growths to remain unilateral.

ETIOLOGY.

As far as my records go, I can find no evidence of any constitutional diathesis or impairment of the general health standing in any causative relation to this affection; indeed, the large majority of my cases were in excellent health. Heredity appears to play no part in causation. In 102 cases only ten knew of any relative who had polypi, one a mother (doubtful), three a sister, three a brother, one a father and two a grandfather. These cases are so few that one seems to be justified in considering them simply coincidences. Of 146 cases 76 were males and 70 females. These figures lend only a slight support to the statement, generally found in textbooks, that these growths are more common in males. More than half of the cases (78) were between thirty and fifty years of age. There were 29 between twenty and thirty, and the same number between fifty and sixty. The extremes were one at thirteen and one at seventy-eight. In 37 cases there existed a deformity of the septum, causing obstruction, more or less marked, of one nostril. Twenty-one of these are recorded as deviation, 11 as a ridge, and 5 as ridge and deviation. Small spurs and ridges and slight deviations were not considered. Bearing in mind the frequency of the occurrence of septal deformity without nasal polypi and *vice versa*, it seems very doubtful if the former ever stands in any causative relation to the latter. I should rather be inclined to the opinion (which, it seems to me, has some foundation in fact) that any injury to the nose which might result in a deformed septum might also bring about a condition favorable to the growth of polyps. This leads me to speak of the theory, expressed by Macdonald, that polypi begin with a localized inflammation of a mucous surface followed by the formation of edematous granulations, which later become covered with epithelium and form what we recognize as polypi. He states further that they may also begin by the accumulation of small round cells in the muco-periosteum, which gradually project from the surface until covered only by epithelium. It certainly seems most plausible to suppose that some cases of nasal polypi have their origin in granulation tissue. Such a theory would explain the fact just mentioned, which it seems to me has not been given the importance it deserves, that some of these cases trace their origin very directly to an injury to the nose. A neglected injury to the nose, with its attendant nasal obstruction, impairment of the circulation by pressure, and irritating muco-purulent or purulent discharge from the injured portion, might quite conceivably result in the formation of edematous granulations which would eventually develop into full-fledged polyps. Bosworth says

that a case has been reported by Gerdy, in which they occurred as a result of a fracture of the vomer. Downie reports a case of a large polyp in the left nostril of a woman aged seventy-four, which she considered the result of a blow on the head received in early life. Unfortunately, as I have said, the question of injury as a routine one was omitted from my records; nevertheless, I find that five of my cases traced the beginning of nasal obstruction to a blow on the nose. It seems to me that injury to the nose may be a factor in causation oftener than we have been accustomed to think, and that it might be profitable to question patients regularly on this point. This idea of the causative influence of previous injury is especially interesting in the light of the statements of Jonathan Wright regarding the blood supply of the mucosa. Any injury to the canals in which the arteries and veins lie would affect the veins more than the arteries and cause that edematous condition of the mucosa which may develop into polypi.

Another predisposing cause of the growth of nasal polypi is suppuration of one of the accessory sinuses. Again in this condition we undoubtedly have a similar disturbance of the "bony canals" of the blood supply. Macdonald says: "Generally speaking, when we have suppuration we find more or less development of granulation tissue, which tissue may be ultimately indistinguishable histologically from ordinary large polypi." While it is generally accepted that nasal polyps by obstructing the nose may lead to suppuration of one or more of the accessory sinuses, it is also true that a discharge of pus from a sinus may cause a growth of polypi or "edematous granulations histologically indistinguishable," which are not cured until suppuration ceases. Of 49 of my cases in which the purulent discharge was due to a sinus affection, in one the pus came apparently from the antrum only, in 11 from the ethmoid only, in 11 from the ethmoid and antrum and in 26 probably from the ethmoid. In this last group the patients were not seen sufficiently often to make an absolutely positive diagnosis. In those cases in which the discharge was the principal symptom and in which obstruction to breathing was little if at all noticeable, it is probable that the sinus trouble caused the polyps. I have records of several cases which support this view.

In these cases polypoid tissue rapidly disappeared after getting rid of a purulent discharge, leaving a healthy mucous membrane. But in those cases in which the nasal obstruction was the principal symptom, it was generally impossible to determine with any surety which was the underlying condition. In some it was no doubt the ethmoiditis; in others it was equally fair to assume that the ethmoid cells had become infected as a result of the presence of the polypi. In seven of my cases the polyps were bilateral while there was only a unilateral purulent discharge. In these cases the most logical conclusion is that the sinus disease resulted from infection of a nostril already occluded by polypi.

As to the theory of some writers that all nasal polyps owe their origin to ethmoid disease, I will only say one word. As long as many skilled and careful observers see cases in which, after the most painstaking scrutiny, they can find no evidence of ethmoid disease, and as long as there are other conditions which can just as reasonably be considered causes, it seems to me that the burden of proof lies with those who hold this view to show that ethmoiditis exists in these cases and to show us a satisfactory method of determining its existence.

All but about a fifth of the cases gave a history of frequent head colds. Some of these so-called colds were, no doubt, only symptoms of existing polypi. That frequent colds are a factor in other cases is quite probable. They indicate, among other things, an abnormal sensitiveness of the Schneiderian membrane. This membrane thus kept in a more or less constantly congested condition with increased serous transudation, one can readily see how the "water-soaked" condition, spoken of by Bosworth, might be acquired. It is undoubtedly a fact that a profound local vasomotor disturbance is present in a great many cases, and it is hard to conceive that such a disturbance does not stand in a causative relation to the polypi. Its existence is shown by the presence of sneezing and a watery discharge. Frequent sneezing and a watery discharge were noted in about one third of my cases, and asthma, which also shows the constitutional tendency to vasomotor instability, was present in one sixth of the cases. In the few cases, fifteen in number, in which the polyp is put down as single, the pedicle was small, and only a small area of the mucous membrane was affected.

SYMPTOMS.

In a very large proportion of cases, obstruction to respiration is the first symptom which calls the patent's attention to his nose. Sneezing, as I have already said, was marked in about a third of my cases. While often an early symptom, it was by no means always such, not appearing in some cases until considerable obstruction existed. Of 93 cases questioned as to the sense of smell, in 39 it was lost, in 4 much impaired, and in 27 impaired, leaving 27 in whom the sense of smell was presumably about normal. Undoubtedly if all these patients had been subjected to a practical test, it would have been found that the olfactory sense was lost or impaired in a still larger proportion of cases. Two or three of the patients in whom the polyps were unilateral stated that the sense of smell was wanting on the affected side. In many cases the smell does not return after the removal of the growths, due, as Bosworth puts it, to "a certain disorganization which occurs in the mucous membrane lining the olfactory region." The character of the discharge varies from watery to mucous, muco-purulent and purulent. Of 134 cases in which the character of the discharge was noted, in 39 it was watery, in 18 mucous, in 37 muco-purulent and in 32 purulent. In 8 cases the discharge, first noted as watery, became purulent later, owing to the starting up of an ethmoiditis.

SEQUELÆ.

Bronchitis was noted at present in 21 cases, in all probability as a direct result of the obstruction to nasal respiration. Asthma was associated with 10, asthma and bronchitis with 14 and hay-fever with 4 cases, while there were 2 cases of hay-fever

with asthma and 2 doubtful cases of hay-fever. I am inclined to think that it is extremely rare for a nasal polyp to take on a malignant character. No such case has ever come under my observation.

TREATMENT.

The aim of any treatment must be the complete removal of the polypi and the restoration of the mucous membrane to a healthy condition so that there will be no further growth. In the first place, it goes without saying that the growths should be removed with as little violence to the surrounding structures as possible. No one will dispute, I think, that the cold wire snare is to-day the instrument *par excellence* for their removal. This instrument must be supplemented in most cases by the use of cutting forceps of suitable shapes and sizes for reaching the parts affected. Where the polyp is single and growing from a small pedicle, a simple removal is often all that is necessary, and there may never be a recurrence. But in those cases in which the growths are numerous and diffuse, the middle turbinate will usually be found to be so deeply affected by the process that only its thorough removal will suffice to eradicate the disease. I have never used the galvano-cautery or chromic acid to destroy the base of these growths, because their irritating qualities, especially the galvano-cautery, may tend to excite that condition in the mucous membrane which we are trying to get rid of. It is unnecessary to speak of the possible dangers of using the cautery in the ethmoid region. I have thought that the application of 95% alcohol on pledgets of cotton to the site of the growths has been of assistance in preventing the recurrence of polypi in some cases. I often prescribe also the use of the distilled extract of hamamelis in a spray. Alcohol has been long ago recommended by McBride, Griffin, Cohen and others, and I simply wish to add my endorsement to its apparent value.

PROGNOSIS.

The prognosis is largely affected by the perseverance with which a patient returns for treatment as desired. I have already spoken of the difficulty one experiences in making patients follow up treatment. Eighty-three of my cases were under observation for a year or less, and the majority of them were seen only two or three times. And many cases which were under observation for a longer period did not return until again troubled by nasal obstruction. Twenty-five cases were seen at various intervals for more than one and less than five years, and 26 cases were seen in this way for five years or over. In these last two groups of cases no polyps were present one year after treatment in five cases. In 8 cases none were seen more than one and less than five years after the last treatment, and in 13 there were none five or more years after. In 7 cases there was a recurrence in one side but not in the other, one or more years after the last treatment. I have included in the above list three or four cases in which there were present at the last visit one or two minute polypoid excrescences in the region of the middle turbinate, but as these had remained unchanged without treatment for one to three or four years, I felt I was justified in including them among the cured cases.

The points which I wish to especially emphasize in closing are: (1) The question of a previous injury to the nose is to be considered in the etiology of polypi. (2) Probably only a small proportion of cases are caused by sinus disease (usually ethmoiditis). (3) A local vasomotor disturbance, which may be of constitutional origin, stands in a causative relation to polypi in a certain proportion of cases. (4) The removal of the whole middle turbinate will be found necessary in many cases where the growths are diffuse. (5) Many cases of nasal polypi can be cured if patients will return for treatment as instructed.

Clinical Department.

SEPTIC ENDOCARDITIS.

BY A. W. DUDLEY, A.M., M.D., NORTH CAMBRIDGE, MASS.

A REPORT of the following case, which I believe was septic endocarditis, may be of interest. The patient, a girl of twenty-five, well developed and well nourished, though pale, has had albuminuria for three or four years — probably longer. Specific gravity, 1015–1020; albumin, ¼% to ½%. Sediment shows normal blood, some granular and hyaline casts. Otherwise her organs are normal. With care she leads a fairly comfortable life. For the winter of 1902 she was not as well as usual.

On Sunday, May 11, I was called to see her; temperature, 102°; pulse, 120, rising at night to 104° and 130; some soreness and redness of the throat (tonsilitis?). On Monday, Wednesday and Friday of that week, every other day, she had fever rising to 103° or 105°, while on Tuesday and Thursday she was very much improved. This suggested large doses of quinine, which had no effect on the temperature. The plasmodium malariæ was looked for in the blood and not found, and there was a marked leucocytosis (May 23, whites, 36,500).

Beginning in the early part of this week, there was a mixed macular, papular and hemorrhagic eruption mostly on the hands, forearms, feet and legs. This continued to appear in successive crops for two or three weeks, the chills coming so often that it was impossible to say whether or not they bore any relation to the rash. Later she had one large bulla on the left knuckle. This was clear at first but became milky; a culture proved sterile. In the middle of the first week also she had fleeting joint pains with some swelling of the legs. This did not last long, but whether or not because salicylates were used I cannot say.

The urine at this time became very high colored; blood, granular and epithelial casts appeared in abundance; albumin remained about constant.

The condition of the urine, however, seemed to be secondary to the fever, and not the cause of it.

At the end of the first week she was seen by Dr. E. H. Stevens. Malaria could not be excluded, and quinine in large doses was continued. Malignant endocarditis was spoken of. Heart negative. During the second week the fever waves became more frequent, at least one a day, rising at times to 106°. The pulse followed the temperature. The heart showed a slight systolic souffle when in violent action only. Spleen slightly enlarged. During the subsidence of the fever she was bright, gay and felt well. The paroxysm of fever was sometimes preceded by chill, vomiting or restlessness, though generally she was quiet till the temperature reached about 103°, when she became restless, and I began early to give her morphia with quieting effect.

This brings the story up to the end of the second week, when she was seen by Dr. F. C. Shattuck. Malaria at this time could be ruled out. Trichinosis was spoken of to be dismissed (eosinophiles not increased). Pyemia was diagnosed, but the source of the infection was not found. Septic endocarditis seemed possible. Dr. Shattuck found the heart and spleen normal, and did not think the eruption then present due to miliary emboli. He advised a blood culture, and the use of antistreptococcus serum (Parke, Davis & Co., 20 cc. daily) if streptococci were demonstrated, or no organism was found. A blood culture proved negative. The serum was given 210 cc. in nine days, and as no benefit was apparent its use was discontinued.

Beginning with May 22 a three-hourly chart was kept. Up to June 10 (three weeks) the pulse followed the temperature. The interval between the crests of the fever waves varied from twelve to twenty-four hours, with one exception (forty-two hours), and the crest of the wave rose from normal to 105° as the lowest and $106\frac{8}{10}$° as the highest. Physical signs showed nothing new except that on June 9 an extra strong cardiac contraction, every 6 to 33 beats, followed by a slightly prolonged pause, was noted. This was never observed again. The systolic souffle, though still faint, became more distinct, was confined to the apex, not transmitted, and heard only when the heart was in violent action. There were a few short attacks of precordial pain.

June 10 we began using unguentum credé, about 2 drams daily. The afebrile intervals immediately began to grow longer and the fever to diminish. I must say, however, that I think this was accidental and not cause and effect, as a backward study of the chart shows slight indications of such a change before unguentum credé was used at all.

From June 10 to July 12 there were fourteen rises of temperature with intervals of from twelve hours to five days — generally two or three days. The pulse was more affected by the attack, and less regular in the intervals; the systolic souffle became more distinct at the end of that time. The depression between attacks was often severe, though never immediately alarming. Unguentum credé was continued. She seemed to be depending on morphia, for which I could find no substitute.

From July 12 to 28, though often greatly depressed and somewhat exhausted, there was no fever except for two days, and then not above 101°. July 20 and 21 she had two attacks of delirium, lasting one and two hours respectively, pupils normal and reacting to light. July 28 and 30 she had fever rising to 105° each time. This was the last till August 25, when with sore throat and diarrhea the temperature rose to 104°.

Her convalescence worried me for a time, among other reasons because I could not entirely omit the morphia, but this was finally accomplished. Her urine is much as it was before the attack. There is no demonstrable lesion of the heart. She has been better this winter than last. She has had, however, what she has never had before, "rheumatism" of the legs, especially on first starting after a rest. Salicylates do no good.

The treatment, aside from what I have mentioned, was entirely symptomatic: alcohol, strychnia, at times digitalis, morphia, good food. Coffee was craved and allowed freely.

As I said in the beginning I believe this was one of the rare cases of septic or malignant endocarditis which get well — more rare because not grafted on to an old endocarditis. I am aware that this diagnosis cannot be absolute, and is arrived at by exclusion fully as much as by positive signs; and while the cardiac signs were not conclusive, autopsies show that frequently physical signs do not betray even very abundant vegetations.

The association between tonsilitis and rheumatism, and rheumatism and endocarditis is recalled by this case starting with a sore throat, showing rheumatic symptoms after a few days and coincident therewith the septic fever curve.

Besides those mentioned I am indebted to Drs. C. M. Hutchinson and H. G. Lazelle for assistance in this case.

Important points are noted on the chart. The chart for the first ten days is not published.

Medical Progress.

PROGRESS IN PHARMACOLOGY AND PHYSIOLOGICAL CHEMISTRY.

BY M. VEJUX-TYRODE, M.D., BOSTON,

Instructor in Pharmacology in Harvard University.

IT has been repeatedly shown that the various organs contain some substance or substances which are capable of digesting them — autolysis. These observations are of very great importance, because by the study of such processes we may get a closer insight into normal and pathological metabolism.

Martin Jacoby [1] notes specific properties to the autolytic action in different organs. He makes the interesting observation that the products of autolysis in different organs are quite different. In the products of autolysis of the lungs he finds a great deal of albumoses, while in autolysis of the liver he finds practically no albumoses. If the product of autolysis of the lung containing a great deal of albumose is treated with extracts of liver, practically all the albumoses disappear. He concludes, therefore, that autolysis is carried on by very different ferments in different organs.

[1] Beitr. z. Chem. Physiol. u. Path., No. 3.

Alfred Reh[2] found as products of autolysis of ox lymph gland, thymin, leucin, tyrosin and ammonia.

O. Shumm[3] found as products of autolysis of the spleen at first much albumose, which later disappeared and were replaced by lysin, ammonia, leucin and tyrosin.

Fritz Baum[4] worked up the constitution of a new aromatic body from pancreatic auto-digestion called skatosin.

Leo Langstein[5] proved the undoubted presence of albumose in the blood.

Waldemar Stade[6] confirms Volhard's observation concerning the presence of a fat splitting ferment in the stomach, and even recommends a further study with a view of determining the efficacy of the stomach by a quantitative determination of this ferment.

N. Sieber[7] found that oxidizing substances, such as hydrogen peroxide and calcium peroxide as well as plant and animal oxidases, as horse fibrin, destroy the efficacy of toxins not only in vitro but in living organisms.

Erich Harmark[8] found that uranium, mercury and copper are much more toxic to the young salamander than iron; also that arsenic has a relatively very low toxicity.

R. Magnus[9] showed that ammonia gas was never absorbed by the lungs and that it was not excreted by these organs even when injected in large quantities into the pulmonary arteries.

E. C. van Leersum[10] demonstrated that equimolecular solutions of sodium sulphate, sodium nitrate and sodium acetate have the same reviving influence as normal salt solution after fatal hemorrhage.

Hildreth[11] recommended preparations of apocynum cannabinum as superior to digitalis in cases of a dropsical effusion, because they do not cause the cumulative action and the other untoward effects of digitalis.

Tunnicliffe[12] finds phenolphtalein a very efficacious purgative in the dose of 0.1 to 0.25 gm.

Hirsch and Beck[13] made determinations of the viscosity of the blood in Bright's disease, and found but rarely an increased, usually a decreased or normal one. They concluded therefore that the hypertrophy of the heart accompanying these cases cannot be explained by increased resistance due to increased viscosity.

Fritz Rosenfeld[14] found an increase in the volatile fatty acids in the urine in case of gastric ulcers, with hyperacidity or normal acidity also in cases of carcinoma of the stomach with sub- or anacidity. He found a decrease in cases of retention with subacidity.

Mathes[15] discovered a true proteolytic ferment in the urines of dogs with extirpated stomachs. Like pepsin, it digests proteid in acid solutions.

Zoepffel[16] agrees that the anesthetics containing halogens are as a rule more depressent to the heart than others, but he believes that the degree of depression is not exactly proportional to the amount of halogen in a compound.

K. Wittmack[17] believes that quinine affects the ear not by producing congestion, as was formerly thought, but by producing an ischemia exactly as in the eye.

Otto Cohnheim and Franz Soetbeer[18] experimented on young dogs with a modification of Pawlow's method to see whether young animals have gastric juice, and if so, whether it is also produced by some reflex action analogous to the reflex action in adults. They found that sucking in itself produced a secretion of gastric juice.

Joh. Kropil[19] uses mesotan (methoxy methylester of salicylic acid) in a solution of olive oil. He rubs it into the skin, especially over rheumatic points. He claims that this form of treatment gives the good effect of salicylates without their undesirable ones.

Bromipin, a compound of bromine with sesame oil, was given by A. Rahn in clysters or in milk or tea with good results.

Kullman[21] made observations on prisoners to see if the food of prisons has any influence on the secretion of the gastric juice, and found that hydrochloric acid is always diminished or absent in 47% of the cases. This is not due to the psychical condition, but mainly to gastritis.

F. Soetbeer and Ibrahim[22] found that after ingestion of water the urine purin bases are not increased, but the nitrogen in the feces is increased.

A. Rydygier[23] studied the functions of the kidneys by cryoscopy under chloroform anesthesia, and found no influence on normal kidney but much disturbances when the kidney was diseased; he therefore regards kidney disease as a contraindication to the use of chloroform.

R. Traussig[24] observed over 50% decrease in the blood pressure after the administration of iodipin, and ascribed this result to a dilatation of the splanchnic blood vessel. He therefore recommends it in lead colic.

C. L. Klotz[25] and Mangel[26] both injected collargol into the circulation of patients with septic endocarditis, and obtained no undesirable results. Klotz obtained marked beneficial effects in his case.

J. Danysz[27] showed that radium produces destruction of the epidermis and cutis when brought in contact with the skin of a guinea pig. It produces tetanic convulsion when brought in contact with the spinal cord.

R. Lepine[28] found that if dog's blood to which sugar has been added stands at a temperature of 38° C. with a current of oxygen passing through it, 30% of the sugar disappears in one hour.

[28] Ibid.

Blood of asphyxiated animals, venous blood or blood of an animal having received a subcutaneous injection of adrenalin all fail to show this glycolysis.

J. Justus,[29] by a very sensitive method, was able to demonstrate iodine in the thyroid, thymus, lymph glands, kidneys, spleen, suprarenals and testicles.

J. Haberman[30] confirmed the observations of Vogel and Kissling by finding hydrocyanic acid in tobacco smoke. He found from one-three-hundredths to one-one-hundredth as much as nicotine, a quantity which is insignificant compared with nicotine as far as action is concerned. Since he could obtain no trace of hydrocyanic acid by wet distillation of tobacco, it is very probable that this found in smoke was formed by burning.

Inouyer and Saiki[31] found an excess of lactic acid in the urine after epileptic attacks, which they attributed to insufficient supply of oxygen during the attack and not to disturbance of the liver.

A. M. Luzzato,[32] while studying the physiology of oxalic and oxaluric acids, found that the excretion of oxalic acid is increased by the injection of uric acid, and that oxaluric acid is completely transformed to oxalic acid in the living organism.

Fr. Hupfer[33] found that quinic acid exerted no influence upon the excretion of uric acid and therefore advises against the use in gout of such quinic acid preparations as urosin sidonal, urol, chinatropin, ursal, urapherin, uropheninbenzoate and urotropine salicylate.

E. Schülz and N. Castro[34] studied the hemicellulose, which forms the cell walls of the seed and cotelydon of lupinus lutus. They find this substance susceptible to partial digestion by diastase, taka-diastase, ptyalin and pancreatin. They believe that this substance is dissolved in the plant cells by a ferment action and subsequently used for the nutrition of the plant.

Aristido Kanitz[35] obtained maximum trypsic digestion in the presence of the hydrates of barium, calcium and strontium in about the same ionic concentration. He therefore concludes that the influence of the hydrates in digestion is dependent on the concentration of the hydroxylions.

Ernst Darmstaedter[36] describes a new method for the quantitative estimation of oxybutyric acid based on its transformation to crotonic acid by 50% sulphuric acid. The results which he obtained are very good, and if confirmed by others the method will be valuable, since no good methods existed before. The best, that of Magnus-Levi, was very far from accurate and tedious in carrying out.

Friedrich Kruger[37] found changes in the absorption bands of hemoglobin after treating it with chloroform. He concludes that chloroform does not only precipitate hemoglobin mechanically but also changes it chemically.

Gustav Embdem and Franz Knoop[38] could not find during the absorption a transformation of albumoses to coagulable proteids or to crystallizable substances, as respectively Hofmeister and Cohnstein, but he finds that albumose is absorbed as such and is present in the blood.

Friedel Pick[39] experimented with extracts of liver, kidneys and blood in reference to their diastatic properties. He finds, as others, that the liver does not alone possess this property, but that the kidney does possess it even in a higher degree. He finds that the diastatic ferment in the liver is destroyed by cooling and its activity is decreased by quinine and hydrocyanic acid in great enough concentration.

B. Friedman[40] finds that creosotal rapidly decreases fever and dullness in pneumonia, and he concludes that this agent acts as an antiseptic to kill or retard the growth of the bacteria causing pneumonia.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

TWENTY-FOURTH ANNUAL MEETING, WASHINGTON, D.C.

The President, DR. MAURICE H. RICHARDSON in the chair.

SECOND DAY, MAY 13, 1903.

PROF. JOH. v. MIKULICZ-RADECKI, Breslau, Germany, read a paper entitled

SOME CONTRIBUTIONS TO THE SURGERY OF THE GASTRO-INTESTINAL TRACT,

in which he divided the subject into the following topics: (1) Cardiospasm and its treatment; (2) peptic ulcer of the jejunum; (3) the operative treatment of severe forms of invagination of the intestine; (4) operation on malignant growths of the large intestine, and discussed each one at some length.[1]

MR. B. G. A. MOYNIHAN, Leeds, England, read a paper on

THE SURGERY OF THE SIMPLE DISEASES OF THE STOMACH,

in which he stated that the great majority of such cases susceptible of successful treatment by surgical measures are due to ulceration or to its complications and results. These conditions were considered by the author under the following heads:

(1) Perforation of gastric or duodenal ulcers.
(2) Hemorrhage from gastric or duodenal ulcers.
(3) Chronic ulcer; its various clinical types.
(4) Hour-glass stomach.

After dealing at considerable length with the symptomatology and treatment of these conditions, and laying especially stress upon the necessity for individualizing the cases, he gave the following résumé of the cases upon which his paper was based[2]: Perforating gastric or duodenal ulcer, 12 cases, 6 recoveries; gastro-enterostomy for chronic ulcer, etc., 70 cases, 1 death; pyloroplasty, 3 cases, 0 deaths; hour-glass stomach, 15 cases, 3

[1] See JOURNAL, cxlviii, p. 608.
[2] See JOURNAL, cxlviii, p. 611.

deaths; gastroplication, 1 case, recovered; excision of ulcer for hematemesis, 1 case, died.

These two papers were discussed by DRS. W. W. KEEN, Philadelphia; W. J. MAYO, Rochester, Minn.; WM. L. RODMAN, Philadelphia; LEONARD FREEMAN, Denver; J. M. T. FINNEY, Baltimore; L. NcLANE TIFFANY, Baltimore; N. B. CARSON, St. Louis; and B. FARQUHAR CURTIS of New York; PROFESSOR TIEMANN of Leipsic, and closed by PROFESSORS MIKULICZ and MOYNIHAN.

PAPERS ON THE THERAPEUTIC VALUE OF THE X-RAYS IN SURGERY.

DR. ARTHUR DEAN BEVAN of Chicago read a paper entitled

THE THERAPEUTIC VALUE OF THE X-RAY.

DRS. WM. L. RODMAN and G. E. PFAHLER read a paper entitled

THE VALUE OF THE X-RAY IN SUPERFICIAL EPITHELIOMATA AND TUBERCULOSIS,

quoting the following advantages of the treatment as given by Pusey:

(1) It is painless; (2) it destroys diseased tissue but leaves healthy tissue in its place; (3) it leaves a minimum scar; (4) it can be used when the surrounding tissue cannot be sacrificed; (5) it relieves pain and induces sleep.

The paper was closed with the following conclusions:

(1) The length of time required for the cure of epitheliomata is longer than by surgical or caustic treatment, while the cosmetic results are better. The dangers are proportionate to the urgency of the treatment as indicated by the degree of malignancy. It should only be recommended in cases that are inoperable either because of the extent of the growth or its location.

(2) It is probably the best means at our command for the treatment of superficial tuberculosis, and gives better cosmetic results.

(3) It should follow all operations for malignant disease or tuberculosis with the twofold object of stimulating the healing process and of preventing a recurrence. In some cases it may be of an advantage to give a short course of treatment before operation, to destroy the outlying portions of the growth and make such operation of a less formidable nature.

DR. WILLIAM B. COLEY, New York, read a paper entitled

FURTHER OBSERVATIONS ON THE INFLUENCE OF THE ROENTGEN RAY UPON SARCOMA,

in which he stated that from Feb. 1, 1902, to May 11, 1903, he had treated at the General Memorial Hospital 36 cases of inoperable sarcoma, the pathological classification of which was as follows: Round-celled, 21 cases; spindle-celled, 6 cases; mixed-celled, 2 cases; melanotic sarcoma, 1 case; osteosarcoma, round-celled, 1 case; type of cell doubtful, 5 cases.

He stated that in four cases which he had reported to the society last year the tumors had entirely disappeared, but in every case there has since been a recurrence. He then gave a brief history of the physical condition and treatment of several cases, and expressed the opinion that the x-ray has a much more powerful effect upon sarcoma than carcinoma.

In regard to the relative merits of the toxins and x-rays in inoperable sarcoma, he felt that the time had been too short and experience too limited thus far to definitely decide this question. He had noted, however, in several cases of inoperable round-celled sarcoma, in which the toxins had been tried and failed, the x-ray had caused entire disappearance of the tumors, but there had been a speedy recurrence in every case. On the other hand, in a much larger number of cases of inoperable sarcoma the tumors have entirely disappeared under the toxin treatment, and remained well from three to ten years after the treatment. The dangers from this method of treatment are burns, toxemia, and metastases resulting from the cells being broken down and carried to other parts of the body. He did not believe that the x-ray method should be employed in operable cases of sarcoma, with the possible exception of carcinoma of the extremities, in which operation would necessitate amputation. In such cases he recommended a brief course of the combined x-ray and toxin treatment, reporting a case of sarcoma of the fibula, which had been treated by this method, which had been treated six years ago by the toxin method, and has remained perfectly well ever since.

DR. ALEX. B. JOHNSON, New York, read a paper entitled

SOME EXPERIENCES IN THE TREATMENT OF INOPERABLE MALIGNANT GROWTHS BY THE X-RAYS,

in which he reported 10 cases, 9 of carcinoma and 1 of sarcoma, 8 died under treatment, and 2 are still alive and have apparently improved, one of them being the case of sarcoma. After a considerable time severe dermatitis was produced in each of these cases, and it was advised the treatment be discontinued at intervals for at least six months. The source of the current was 110 volts direct commercial current. Fifteen-inch spark length Willyoung induction coil. The distance was at first twelve inches, which was gradually diminished to six, as tolerance at that distance became evident on the part of the patient. The surrounding parts were protected by sheets of lead foil weighing 10 oz. per square foot.

These papers were discussed by DRS. WILLIAMS of Boston, W. JOSEPH HEARN of Philadelphia and R. H. HARTE of Philadelphia, and closed by the authors.

DR. WILLIAM B. COLEY, New York, read a paper entitled

RESULTS OF ONE THOUSAND OPERATIONS FOR THE RADICAL CURE OF INGUINAL AND FEMORAL HERNIA PERFORMED BETWEEN 1891 AND 1902.

Out of the 1,003 cases which the author had operated upon between August, 1891, and December, 1902, there were 937 cases of inguinal hernia, 756 of which occurred in males and 181 in females; and 66 cases of femoral hernia, all males. In the 66 cases of femoral hernia there was no mortality and the primary union was obtained in all but one

case, which formed the only recurrence, the balance having remained well from six months to eleven years. The Bassini method for femoral hernia was employed in 16 cases and the purse-string suture (with kangaroo tendon) in 50 cases. Out of the 181 operations upon the female for inguinal hernia there was no recurrence and no relapse, the method employed being practically Bassini's method for the male. There were no deaths in any of these 1,003 cases. In children operations should seldom be advised under four years, the reason being that many of the cases at this age are cured by a truss, but after that age in cases in which a truss has been tried and failed, or cases in which the presence of reducible hydrocele prevents a truss from holding the rupture, operation is advised. In all adult cases under the age of fifty years operation is advised unless there are strong contraindications. Between the ages of fifty and seventy years operation is advised in patients in good health in cases in which the rupture is held with difficulty by a truss. Six hundred and fifty of these cases were found well in from one to eleven years; 708 cases were found well in from six months to eleven years; and 467 in from two years to eleven years. A careful résumé of the literature on the subject and a comparison of the results obtained by other operators were given.

This paper was discussed by DR. A. H. FERGUSON of Chicago and closed by the author.

DR. N. P. DANDRIDGE, Cincinnati, Ohio, read a paper entitled

REPORT OF A CASE OF GANGRENE OF FIFTEEN INCHES OF CECUM AND ILEUM AFTER AN OPERATION FOR APPENDICITIS. RELIEF OF ARTIFICIAL ANUS AFTER REPEATED OPERATIONS.

On opening the abdominal cavity for the purpose of removing the appendix it was impossible to locate it, but there was discovered a mass on the inner side of the colon, above the ileo-cecal valve, beneath the peritoneum and lying on the psoas muscle and overlapping its inner edge. The tumor was removed after ligating an artery which ran through it, and subsequent examination proved it to be enlarged mesenteric glands. This, together with the appendix, which was found behind the cecum, was removed, and the wound closed without drainage, after which the patient progressed well until the evening of the eighth day, when the dressings suddenly became saturated with a thin fecal fluid, and were changed, and the same condition was found again the next morning, and on opening the wound gangrenous tissue was exposed, which increased in extent until a day or two later a section of the ileum nine inches long was washed out, entirely gangrenous. A complete artificial anus was established, a drainage tube inserted, and with this drainage the pus and fever disappeared. At the end of seven weeks a lateral anastomosis between the small intestine and colon was done, in order to partially relieve the artificial anus, but proved to be a complete failure so far as this was concerned. Some months later an end-to-end anastomosis of the ileum and colon was made by the Murphy button, a small fecal fistula remaining in the side. Two attempts were made to close this fistula, and a colostomy had added much to the patient's comfort and diminished still more the size of the opening, which was finally closed by means of pressure from an elastic sponge held in place by an elastic bandage around the body.

This paper was discussed by DRS. A. J. OCHSNER of Chicago and G. R. FOWLER of Brooklyn, N. Y., and closed by the author.

THIRD DAY — MORNING SESSION.

DR. JOHN C. MUNRO, Boston, Mass., read a paper entitled

THE SIGNIFICANCE OF ALBUMIN AND CASTS IN SURGICAL PATIENTS,

in which he stated that, while he believed that there was no doubt that there was danger in operating on a patient whose kidneys are incapable of sufficient elimination, and where there are secondary organic changes, because a patient exhibits a small amount of albumin, hyaline and fine granular casts, with renal cells, the conclusion should not be hastily reached that he is not a fit subject for operation; on the other hand, the presence of any of these symptoms should be sufficient to cause a thorough investigation. He reported a series of 500 cases showing albumin and casts in the urine, not including those, however, that showed renal degeneration, glycosuria, genito-urinary diseases, burns, erysipelas or similar diseases, most of which were subjected to ether anesthesia, and in none of them was it noticed that any renal damage was inflicted. Out of the series of 500 cases 63 died: 8 from shock, 2 after operation for general peritonitis, 5 from pneumonia, 3 from tuberculosis, 19 from sepsis or severe peritonitis, 4 from senility, and, in addition, there were deaths from embolism, malignant disease, cardiac disease, skull fractures and pancreatitis, where the rôle of the urinary organs must have been insignificant. Of the four cases in which death was ascribed to senility, one with cellulitis of the arm had ¼ % of albumin and casts; one with intestinal cancer had profuse diarrhea, one had a strangulated hernia and the fourth died one month after fracture of the femur, showing only the slightest possible trace of albumin with hyaline and granular casts.

This paper was discussed by DRS. JOHN B. ROBERTS of Philadelphia, N. B. CARSON of St. Louis, F. H. GERRISH of Portland, Me., and M. L. HARRIS of Chicago, and closed by the author.

DR. FRANCIS J. SHEPHERD, Montreal, Canada, read a paper entitled

THE TREATMENT OF ANEURISM OF THE EXTERNAL ILIAC ARTERY BY DIGITAL COMPRESSION, WITH REPORT OF A CASE,

in which he referred to the great dangers of surgical interference with the tumor, making amputation of the extremity preferable in many cases to trying to remove the aneurism. He gave a careful résumé of the literature on the subject. The advantages of digital compression are that no apparatus is necessary, the finger being the sole means by which the artery is controlled above the aneurism.

This, of course, requires quite a number of assistants, and does not usually require to be kept up more than twenty-four hours; in the case reported, the pulsation ceased at the end of twelve hours.

This case occurred in a man forty-three years of age, who had strained himself by lifting a heavy weight, and some months afterward a swelling appeared in the left groin, which pulsated; was at first soft and painless, but gradually became harder and seemed to grow upwards into the abdomen. The patient objected to operation, and it was decided to put him on palliative treatment until the session opened, so that relays of students could be secured. He was put on Tuffnell's treatment and ice-bags applied over the tumor, iodide of potassium being given internally, and very little fluid. At the end of twelve hours pulsation had entirely ceased, the pain having been severe after the first four or five hours until the end of twelve hours, being controlled by hypodermic injections of morphine. After twelve hours the patient had no excessive pain, but compression was continued in a moderate degree for twelve hours more, when the leg was wrapped in cotton wool and carefully bandaged, he being kept in bed for a couple of weeks more, and six months after the operation, although the tumor could be easily felt, there was no pulsation and it was very hard.

This paper was discussed by DRS. R. H. HARTE, of Philadelphia, J. F. BINNIE, of Kansas City, Mo., and JAMES T. BRYANT, of New York, and closed by the author.

DR. LEONARD FREEMAN, Denver, Col., read a paper entitled

STRANGULATED LEFT DUODENAL HERNIA, IN WHICH THE SAC CONTAINED THE ENTIRE SMALL INTESTINE, THE CECUM AND A PORTION OF THE COLON,

in which he referred to the fact that the abdominal viscera and peritoneum are subject to various malformations and malpositions, sometimes acquired and often congenital, and unless the surgeon be familiar with these unusual phenomena his diagnostic ability will be curtailed by confusing conditions for which he can find no adequate explanation. The peritoneal fossæ may be responsible for the most remarkable forms of hernia, and this is especially true of the duodenal fossæ. He carefully reviewed the anatomical formation in this region, and reported a case of strangulated left duodenal hernia in a strong, well-devoloped man, thirty-nine years of age. He had always enjoyed good health with the exception of occasional indefinite abdominal pains, and five days before the author saw him he developed a severe ileus, with the usual symptoms of acute intestinal obstruction, with a pulse of 120; temperature subnormal and capillary circulation poor. Immediate operation was performed. On opening the abdomen the cavity was found to be occupied by an immense tympanitic tumor, resembling an ovarian cyst, which could be outlined on each side by passing the hand between it and the abdominal walls. Upon opening the membranous sac it was found to contain the entire small intestine, together with the cecum and some six or eight inches of the colon. There was considerable foul and bloody serous fluid, no traces of which existed outside the sac, showing how completely the inner cavity was separated from the outer. The cecum, which was distended with fluid feces to the size of an infant's head and largely gangrenous, lay in the left upper quadrant of the abdomen, just beneath the spleen, in the vicinity of which the swollen appendix was attached by recent inflammatory adhesions.

In attempting to relieve the condition it was necessary to resect the gangrenous cecum together with some six inches of the large intestine and a considerable portion of the small bowel. In doing this the gut was crushed with an angiotribe, the cut ends invaginated, and the opening closed with an over-and-over suture. A side-to-side anastomosis was then made with the Murphy button between the lower end of the ileum and a loop of the colon in the right iliac fossa; but the patient's resisting powers were so poor and the operation so complicated that death resulted.

This paper was discussed by DR. JOSEPH G. BLOODGOOD of Baltimore, and DR. ELLSWORTH ELIOT of New York, and closed by the author.

DR. B. FARQUHAR CURTIS, New York, read a paper entitled

THYROIDECTOMY AND SYMPATHECTOMY FOR EXOPHTHALMIC GOITER,

in which he referred to the fact that the surgical treatment of this condition has excited much interest of late, owing to the fact that medical treatment failed in many cases, although he believed if the disease had not progressed too far and the patient's circumstances were such as to permit systematic treatment for a sufficient length of time, rest, hygienic measures and proper medication would generally produce a cure, or at least hold the symptoms in check, but there are many cases amenable to surgical treatment that cannot be cured by medicine. However, this treatment is not unattended by dangers, especially acute exacerbations of the symptoms known as thyroidism, which is just as liable, however, to be produced by operation in any other part of the body.

The various operative measures which have found favor are: (1) Thyroidectomy of one half of the gland. Resection of a smaller portion and enucleation of the situs of the tumor appear to be much more dangerous in these cases on account of the greater danger of hemorrhage (Kocher). (2) Ligation of the arteries. (3) Erythyreopexy. (4) Sympathectomy or partial or total excision of the cervical ganglia.

In conclusion he stated that exophthalmic goiter could be cured by both thyroidectomy and sympathectomy, a perfect result being secured in about 60 % of the cases of thyroidectomy, and an immediately good result appears to be the rule in sympathectomy. Sufficient time has not elapsed to judge of the permanence of the cure, but the immediate results are far superior to those of thyroidectomy. The relative mortality of the two would seem to favor sympathectomy (Kocher 4 deaths in 59 cases of thyroidectomy and ligation only; Jonnesco no deaths in 14 cases of bilateral sympathectomy), although in my own cases the result is the opposite. He believed that local anesthesia should be employed, and sympathectomy should be performed only on one side at a time, a sufficient time being allowed to elapse for the patient to recover from the effects of the first operation.

This paper was discussed by DRS. THOMAS W. HUNTINGTON of San Francisco, WILLY MEYER of

New York, BACON, of New Haven, A. J. OCHSNER, of Chicago, GEORGE WOOLSEY, of New York, EMMET RIXFORD, of San Francisco, F. J. SHEPHERD of Montreal, Canada, and JOSEPH C. BLOODGOOD, of Baltimore, and closed by the author.

DR. WILLY MEYER, New York, read a paper entitled

PROSTATECTOMY AND GALVANO-CAUSTIC PROSTATOTOMY (BOTTINI'S OPERATION); THEIR PRESENT STATUS IN THE RADICAL TREATMENT OF THE HYPERTROPHIED PROSTATE GLAND,

which he summed up as follows:

(1) The operations making a direct attack upon the enlarged prostate gland are preferable to those aiming to exert an indirect influence.

(2) We have two useful operative procedures for the direct treatment of the enlarged prostate, that is, prostatectomy and galvano-caustic prostatotomy (Bottini's operation).

(3) In selecting the method indicated in the given case we must individualize and be guided by anatomic, pathologic and social conditions.

(4) Prostatectomy is, of course, the most radical and most surgical procedure; it should be the operation of choice whenever promising success.

(5) Perineal prostatectomy offers advantages over the suprapubic method, since it enables the operator to do the operation under the direct guidance of his eyes.

(6) Debilitated patients who seem unfit subjects for the more radical operation should not be relegated to catheter life, nor should prostatectomy be performed in order "to let them down easy"; they should be advised to have Bottini's operation done.

(7) Surgeons should familiarize themselves with both methods in order to be in a position to do justice to their patients.

(8) It is the duty of those refusing to do Bottini's operation under any circumstances to nevertheless advise patients who ask for more radical relief to have Bottini's operation done, if the operation with the knife seems contraindicated.

(9) Further carefully compiled statistics as to the late results of both operative procedures, preferably in the hands of one man, are desirable in that they will increase our knowledge with reference to the proper selection of the proper method in the individual case.

This paper was discussed by DRS. LEONARD FREEMAN of Denver and A. H. FERGUSON of Chicago, and closed by the author.

DR. CHARLES A. POWERS of Denver reported a case of

DIFFUSE GONOCOCCUS INFECTION OF THE ENTIRE UPPER EXTREMITY.

His patient was a man of twenty-eight years who developed a very extensive phlegmon in the neighborhood of the right elbow joint with concomitant swelling and edema of the entire limb from the pectoral region and shoulder to the ends of the fingers. The gonococcus was recovered from pus liberated by early free incisions, and was also found in a thin serous fluid which escaped at the site of other openings. The course was protracted over many weeks, the patient recovering with stiffened joints.

The author emphasized the fact that systemic gonorrheal infection may invade the tissues in wide variety, the gonococcus having been found in the peritoneum, the pleura, the pericardium, myocardium, endocardium, meninges of the brain and spinal cord, periosteum, perichondrium, muscles and tendon sheaths, bursæ, fascia, the skin, the parotid gland, the kidney and the blood current, as well as the joints.

DR. J. F. BINNIE, Kansas City, Mo., read a paper entitled

MYOSITIS OSSIFICANS TRAUMATICA,

in which he called attention to the fact that bone may be formed in muscle or tendons under several distinct conditions: There may be a process of ossification attacking one muscle after another, myositis ossificans progressiva, producing the ossified man of the freak shows. Oftentimes repeated slight traumata give rise to bone growths in muscle or tendon, examples of such growths being "riders' bone," "drill bone," "cavalryman's bone," and "fencers' bone"; and lastly there is the so-called myositis ossificans traumatica, where a mass of bone forms in a muscle after a single injury, which was the condition with which the paper dealt. The author reported a case occurring in a man aged forty-one, who had received a severe blow on the right forearm two weeks previously while boxing. One week later the tumor was removed and eight months thereafter there had been no recurrence and no disability. The paper dealt fully with the literature on the subject and the various theories of the origin of these tumors.

DR. J. C. BLOODGOOD, Baltimore, Md., read a paper entitled

METHOD OF INSTRUCTION IN SURGICAL PATHOLOGY,

in which he referred to the fact that clinical instruction in the hospital wards and in the outpatient departments always has certain defects and limitations as a complete method of instruction, as he felt that during the time the student spends in the wards, many important surgical diseases had not been seen at all, or so rarely that the student did not get a clear conception of the disease, and in addition it is very difficult for the student to follow the patient throughout the progress of the disease and his after-condition. In the Johns Hopkins Hospital the instruction of the third year medical class in the surgical laboratory is divided into two parts: first, the systematic part, in which the instruction is given by pamphlets, museum specimens, microscopic sections and illustrations; and second, the more difficult or routine instruction, which is limited to the fresh material sent to the laboratory from the operating and autopsy rooms. He then described each of these parts in detail.

(*To be continued.*)

Recent Literature.

Atlas and Epitome of Diseases of the Mouth, Pharynx and Nose. By DR. L. GRUNWALD, of Munich. Second edition, revised and enlarged. Authorized translation from the German. Edited

with additions by JAMES E. NEWCOMB, M.D., Instructor in Laryngology, Cornell University Medical College, etc. With 102 illustrations on 42 lithographic plates, and 41 figures in the text. Philadelphia and London: W. B. Saunders & Co. 1903.

This is a companion volume to the one on the larnyx, edited by Dr. C. P. Grayson' and published in 1898. The two books combined offer one of the most attractive manuals on the diseases of the upper respiratory tract. This is especially true for the instructor, who can use the excellent plates to the best advantage in place of, or in addition to, his clinical teaching. Stated briefly, this book is about equally divided between lithographic colored plates and text. The former show pathological lesions drawn from actual cases, the histories of which are given in sufficient detail. The drawing and coloring are absolutely first class and the selection of cases typical of the lesions. There are also a few microscopical sections in color.

The second half consists of about two hundred small pages of text, covering the diseases and treatment of this part of the body. It cannot of course be expected to be exhausted in this space. The different pathological conditions are subdivided as little as possible, and general principles emphasized. The work of the author, especially in the subject of accessory sinus disease, is so important that a concise monograph on this and other subjects is of great value. If the reader does not expect to find a complete textbook he can hardly fail to be well pleased by these two volumes.

Manual of Bacteriology. By ROBERT MUIR, M.A., M.D., F.R.C.P., (Ed.), Professor of Pathology, University of Glasgow, and JAMES RITCHIE, M.A., M.D., B.Sc., Reader in Pathology, University of Oxford. American edition (with additions), revised and edited from the third English edition by NORMAN MACLEOD HARRIS, M.B., Associate in Bacteriology, Johns Hopkins University. 965 pages with 170 illustrations. New York and London: The Macmillan Co. 1903.

The appearance of the third edition of this manual will be welcomed both by students and practitioners. It has come to be recognized both in this country and in England as the standard textbook of medical bacteriology.

The scope of the work is restricted to a consideration of the pathogenic micro-organisms. It deals, however, not only with bacteria but the disease producing protozoa and fungi as well. The hemameba of malarial fever, the ameba coli and the blastomyces are carefully described. It is to be regretted that Mallory's admirable method of staining the amebæ differentially is not given.

The value of the book is distinctly increased by the additions and alterations of the American editor, and the statements of such an able bacteriologist as Dr. Harris carry with them the stamp of authority. We think, however, that the changes he has incorporated should have been distinguished by brackets, or otherwise, from the original text, in justice both to himself and to the English authors.

A comparison with the second edition issued in 1899 shows that although much new matter has been added, the work of revision and elimination has been so thorough that the length of the volume remains practically the same. The size of the leaves is increased, and the book is printed from larger and better type. There are 44 more illustrations.

The authors have kept pace with the many advances made during the past three years. A new chapter on the bacteriology of the air, soil and water has been inserted, and the chapter on immunity has been amplified and includes an account of the recent important work and an explanation of Ehrlich's lateral chain theory.

The section devoted to tuberculosis is excellent, and the results of the recent studies of the varieties of tubercle bacilli and other acid-fast bacilli is clearly presented. We wish that Dorset's egg medium had been mentioned, as it is readily prepared and gives luxuriant growths of the tubercle bacilli.

The statement that the blood from paratyphoid patients never clumps *Bacillus typhosus* will have to be modified in view of the recent observations of Hünermann and others.

Atlas and Epitome of Traumatic Fractures and Dislocations. By PROF. DR. H. HELFERICH, Professor of Surgery at the Royal University, Greifswald, Prussia. Authorized translation from the German, edited by JOSEPH C. BLOODGOOD, M.D., Associate in Surgery, Johns Hopkins University, Baltimore, Md. Fifth edition, revised and enlarged. With 216 colored illustrations on 64 lithographic plates, and 190 figures in the text. Philadelphia and London: W. B. Saunders & Company. 1902.

Professor Helferich has written a book to serve as a reference book for the use of physicians in general practice, and as an introduction to the important subject of fractures and dislocations. This is the fifth edition of the book, and many skiagraphs have been added to it. The more common fractures are described at length, the rarer fractures are simply alluded to, and the book is profusely illustrated. The pathology of the various injuries is gone into very thoroughly, but the treatment of injuries is not elaborately dealt with. For reference the book will be very valuable, and it is a very attractive volume. The American editor of the volume has tried to supply the deficiencies that exist in treatment. Many of the methods advocated by Professor Helferich have long since been abandoned by Americans.

Clinical Lectures on Surgical Subjects. Delivered in University College Hospital by CHRISTOPHER HEATH, Past President of the Royal College of Surgeons of England, Emeritus Professor of Clinical Surgery in University College, London, and Consulting Surgeon to University College Hospital. Second series. Philadelphia: P. Blakiston's Son & Co., 1012 Walnut Street. 1902.

Mr. Heath has placed us under renewed obligations in contributing these clinical lectures, which are upon special subjects in which Mr. Heath is interested. The conversational style of the writer and his distinctly practical way of looking at a subject come out very strongly in these lectures.

Clinical Essays and Lectures. By HOWARD MARSH, F.R.C.S., Surgeon to and late Lecturer on Surgery at St. Bartholomew's Hospital, Consulting Surgeon to the Hospital for Sick Children, President of the Clinical Society of London, Hon. Member of the Medical Society, State of New York. London: J. & A. Churchill, 7 Great Marlborough Street. 1902.

In this little volume Mr. Marsh reprints certain selected essays and lectures that have been published elsewhere. His desire has been to give some of the knowledge that he has acquired during his years of experience in the diagnosis and treatment of disease. Some of the essays are of more than ordinary interest; for example, that on "Growth as an Agent in the Production and in the Removal of Deformity," and that on "The Etiology of Making Mistakes in Diagnosis," have distinctly a "Hunterian" character. The article on "Senile Tuberculosis" is of great value, in that the condition is not commonly recognized by medical men. Mr. Marsh has evidently observed accurately and reasoned carefully and soundly. It is to be regretted that more clinicians do not place their observations in a more permanent form. The whole volume is of great interest, and will well repay careful study.

The Practical Medicine Series of Year-Books, comprising ten volumes on the year's progress in medicine and surgery. Issued monthly. Under the general editorial charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume II. *General Surgery.* Edited by JOHN B. MURPHY, M.D., Professor of Surgery, Northwestern University Medical School. November, 1902. Chicago: The Year-Book Publishers, 40 Dearborn Street.

This year-book on general surgery, edited by Dr. Murphy, is very complete. It covers essentially the advances that have been made in surgery during the preceding year. The editorial comments are of a great deal of value in that they give the practical experience of the editor. We have kept a copy, for a time, as a reference book, to test its value, and we find that as a book of reference it is of positive value.

SEIZURE OF DOGS.

On June 23 the board of aldermen of the city of New York passed an ordinance providing for the seizure of all dogs found in the streets which are not in leash or else so muzzled as to prevent their biting. Owners of licensed dogs captured unmuzzled must be notified, and on payment of $3 they may redeem the animal within three days. The Society for the Prevention of Cruelty to Animals is charged with the work of gathering in and disposing of unmuzzled dogs, but the aldermen neglected to make any appropriation, and as the society has no funds to use for this purpose, the ordinance is not likely to be carried into practical effect until some provision has been made for the expense. All funds collected through the operation of the ordinance, it is stated, will go to the city chamberlain.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JULY 2, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
283 WASHINGTON STREET, BOSTON, MASS.

PRELIMINARY TRAINING OF NURSES.

WITH the gradual raising of standard in various departments of educational work, it is not unnatural that renewed attention should be directed to the preliminary training of nurses. Apparently nursing has ceased to be a trade, and has become a profession with certain definite standards. The last few years has seen the organization of nurses in various parts of the country, and with this organization must come a definite feeling of the importance of the body to which they belong and of the necessity of forcing this recognition upon people at large. It has been noticeable for the past few years that both nurses themselves and physicians interested in the general problem have been suggesting a certain more definite preliminary training for women intending to take up the profession of nursing.

In the issue of the JOURNAL for Nov. 21, 1901, Dr. R. C. Cabot expressed the hope that in the course of time nursing might be made a "liberal profession." To this end he made various pertinent suggestions regarding the reform of training schools, and came to the following general conclusions: That the instructors of nurses should be paid; that nursing should be taught by nurses; that the preparation for private nursing should be taught in private families and by private nurses; and that the curriculum should contain liberal as well as purely technical studies.

Again in our issue for June 18, 1903, Dr. Francis P. Denny discusses the need of an institution for the education of nurses which shall provide for their training independent of the hospitals, before undertaking the actual work of hospital nursing. Dr. Denny believes that the nurse's diploma should come from this institution rather than from the

hospital, and that its award should represent satisfactory work in the preliminary course, together with service in a hospital in which there was a high standard of nursing.

All this points clearly in the direction we have indicated, that physicians as well as nurses are demanding more completely trained women, and that the educational standard must thereby be definitely and permanently raised. The matter seems to have reached a more or less definite solution in Philadelphia, where there has recently been organized, under the auspices of the Drexel Institute, a preparatory course of instruction for nurses. This movement has been instigated by Dr. S. Weir Mitchell and the superintendents of the leading training schools of the city. After due consideration of the question, members of the American Society of Superintendents of Training Schools for Nurses have reached the conclusion that if a preparatory course of training in scientific branches can be given, it would afford much needed relief for nurses during the first year of their actual technical training. The course of instruction which has been mapped out in the preliminary announcement includes such subjects as anatomy, physiology, medical chemistry, domestic science and economics, English, vocal expression, hygiene, bacteriology, and what is no doubt of equal importance, physical training in the gymnasium. Public lectures on art, science, literature, etc., which are from time to time given at the institute during the winter, are also to be open to the student. It is proposed to give a certificate to those who complete the full course, and the leading training schools of the city are to give preference to candidates who hold a certificate of the preparatory course.

This experiment, if we may call it by that name, is practically sure of success. Whenever standards have been raised, whether in medicine or other lines of work, there have always been students in sufficient numbers to meet the added demands made upon them. That this will also be true of nurses there cannot be the slightest question, and in general we must be in sympathy with a movement which tends to the betterment of what is becoming more and more distinctly professional work.

The consequences, however, of this elevation of standard and consequent extra time demanded will, no doubt, be felt in the increased payment which must be made to such highly-trained women. This we cannot regard as an unmitigated blessing. The standard fee of three dollars a day has long been established, is in general adequate for the work demanded, and we should regret for various obvious reasons to see a definite and permanent increase in the amount demanded by the best nurses. Already certain obstetrical nurses, and no doubt others, are asking and getting twenty-five dollars a week. We have not the slightest desire to begrudge this or any other amount which may be legitimately earned, but we must distinctly face the fact that a new class of nurses will be developed, inferiorly educated, who will in consequence give their services for smaller amounts. We need nurses for all classes in the community, and particularly for that class of persons whose means are moderate, but whose requirements are the same as with persons of much greater financial resources. In the development of nursing as a profession we certainly do not wish to lose sight of nursing as a humanitarian art, nor do we wish to lose sight of what practical nursing really is. We are somewhat skeptical as to the claim of nursing to be ranked as a "liberal profession," and we shall regret the day, which seems close upon us, when women trained as nurses will find it beneath their dignity to do the hard, menial, disagreeable work, which, after all, constitutes the essence of their calling. Even under existing conditions many nurses are far from being an unmitigated blessing in the household, and if further education is to increase this deplorable tendency we must forthwith call a halt. In the meantime we await with much interest the developments which are sure to come.

THE MORTALITY OF TENEMENT HOUSE POPULATIONS.

IN many of the large cities of Great Britain a very considerable portion of the population lives in single-room tenements under conditions very unfavorable to the occupants. In such cases, isolation of infectious diseases is practically impossible, unless the patient is taken at once to a hospital for treatment.

Dr. J. B. Russell, the former efficient health officer of Glasgow, has vividly described existing conditions in that city, in contrasting the life of the poor with that of the wealthy population: —

"Last of all, when *you* die, you still have one room to yourself, where in decency you may be washed and dressed and laid out for burial. If that one room were your house, what a ghastly intrusion you would be! The bed on which you lie is wanted for the accommodation of the living. The table at which your children ought to sit must bear your coffin, and they must keep your unwelcome company. Day and night you lie there, until with difficulty those who carry you out thread their tortuous way along the dark lobby and down

the narrow stair through a crowd of women and children." [1]

Dr. Russell has here graphically described a death among the abodes of the poor, but when the death is from infectious disease, the conditions are still worse, since the added danger of infection to the remaining members of the family only doubles the distress of the household.

Much has been done to alleviate these conditions by the enactment of ordinances regulating the amount of air space for each individual in such apartments and by the provision of hospitals for infectious diseases, but it still remains true that the death-rate of people living under such conditions is not only much greater than what it ought to be, but also very much greater than that of the population living in more spacious apartments. Much of this increased mortality must undoubtedly be charged to the account of poverty and intemperance, both of which are usually concomitants of the narrow and cramped conditions in which such people live.

In a recent paper read before the Royal Philosophical Society of Glasgow, by Dr. A. K. Chalmers, the present health officer of the city, [2] the author states his intention first to eliminate as far as possible the effect of external conditions, and to ask what part the house, considered simply as a place of residence, plays in the life history of its inmates, and to what extent its effect becomes an appreciable factor in the production of the death-rate. For this purpose he takes the population of the city at the last census, and arranges it in groups, distinguishing between the numbers occupying one, two, and three apartment houses, and those of all other sizes, and against each group places the deaths occurring during the census year 1901 and their equivalent rates.

Of the several tables published in this interesting paper, the following is selected as showing the conditions prevailing in Glasgow.

The contrast presented in Column 3 at once arrests attention. In a year in which the death-rate for the city was less than 21 per 1,000, it is scarcely exceeded by that of the two-apartment population (which forms nearly one half of the whole) and not even approached in the population occupying tenements of larger size. Yet in this same year the death-rate among the one-apartment population was 33 per 1,000, and this not in one district only, but calculated over nearly one seventh of the population distributed widely throughout the city.

[1] Life in One Room, by Dr. J. B. Russell, Glasgow, 1882.
[2] The Death-rate in One Apartment Houses: An Inquiry based upon the census returns of 1901, by A. K. Chalmers, M.D., D.P.H., Glasgow, 1903.

DEATHS AND DEATH RATES FROM "ALL" AND FROM "CERTAIN" CAUSES IN HOUSES OF SEVERAL SIZES. GLASGOW, 1901.

1	2	3		4		5		6	
Size of Houses.	Census Population.	All Causes.		Infectious Diseases		Phthisis.		Respiratory Diseases.	
		Deaths.	Death-rate per 1,000.	Deaths.	Death-rate per 1,000.	Deaths.	Death-rate per 1,000.	Deaths.	Death-rate per 1,000.
1 room.	104,128	3,405	32.7	771	7.4	247	2.4	792	7.6
2 rooms.	348,731	7,418	21.3	1,576	4.5	620	1.8	1,600	4.6
3 rooms.	151,754	2,081	13.7	290	1.9	178	1.2	362	2.4
4 and more rooms.	136,511	1,533	11.2	139	1.0	99	0.7	272	2.0

The general death-rate of the city was 20.6 per 1,000. The best tests of unsanitary conditions are a high infantile mortality, excessive prevalence of infectious and of respiratory diseases and a high diarrheal mortality. These were all to be found in this one-room community. Thirty-one per cent of the total number of deaths under five years occurred in these one-room tenements, and the death-rate from phthisis among them was also high. It is also a significant fact that 42% of the uncertified deaths and 38% of the deaths of illegitimate children occurred in these one-room tenements.

Of the total population of Glasgow, according to the census of 1901, 104,128 lived in one-room and 348,731 in two-room tenements, these altogether constituting about three fifths of the total population of the city.

In interpreting the meaning of the term "one-apartment house" Dr. Chalmers says: "We use the term one apartment for convenience, but does it not represent rather a manner of life than a mode of occupancy? We have many one-roomed tenants in houses of larger size, many also who in our one rooms reach standards, both of hygiene and morality, which guard us against any such arbitrary distinction as the simple question of size entails. But, in the main, the term may be retained to indicate an elementary stage in civic development, a stage in which the Scriptural injunction to wash and be clean has but limited currency."

There is but little information bearing upon this point in the reports of the large cities of the United States. The most suggestive data are to be found in the United States census volumes prepared by Dr. J. S. Billings for the census of 1890.

In the volume containing the figures for Boston it appears that the death-rate of Ward 8 (the Leverett-street District) was 34.6 per 1,000, and that of South Boston (Ward 13) was 33.0, and that of the North End (Ward 6) was 31.7, during the six years embraced in the report, while that of the Back Bay District (Ward 11) was only 15.8, and

that of the Fen District (Ward 22 A) was only 13.6 per 1,000.

When different diseases were considered the differences were still more striking. In Ward 8, with 180.9 persons to the acre, the death-rate from consumption was 671 per 100,000 living, and in Ward 13 it was 588 per 100,000, while in Ward 9 B, with 89 persons per acre (the Beacon, Chestnut and Pinckney street District), it was only 93.8 100,000.

These striking differences, however, appear to be due more to social conditions, such as poverty and intemperance, than to the simple factor of overcrowding in apartments large or small and of a greater or smaller number of rooms to each family.

APPENDICOSTOMY.

FOR the benefit of those of our readers who are not surgeons, and who have not attempted to keep pace with the somewhat hybrid terminology which has developed within the past few years, we desire to call attention to a unique operation first done by Weir, which is again reported by Willy Meyer of New York in the current number of the *Medical News*. Meyer gives to this operation the name "appendicostomy," which, no doubt, to many minds will at once convey a definite meaning. To those who are less familiar with recent surgical nomenclature, however, we beg leave to state that this operation consists in making use of the normal appendix as a means of gaining entrance to the cecum, for the purpose of irrigating the lower bowel. In a case of ulceration of the large intestine, Meyer succeeded in inserting a drainage tube into the lumen of the appendix, after suturing the organ to the abdominal wall, and thereby affording a channel for flushing the diseased bowel. Under this treatment, repeated daily or every other day, the ulcerations decreased, and the patient gained materially in weight. The technical details of the procedure we will not discuss; our intention is merely to call attention to an unusual operation of great ingenuity, if of somewhat limited applicability. Meyer says of it: "I certainly consider Dr. Weir's proposition a valuable addition to our operative resources, besides presenting the fascinating idea of making use of this otherwise absolutely useless organ." To find a positive use for the appendix, we agree, is certainly a surgical triumph of no mean order.

MEDICAL NOTES.

UNIVERSITY OF CALIFORNIA PUBLICATIONS IN PHYSIOLOGY. — It is reported that a series of publications on work in physiology at the University of California will be undertaken under the editorship of Prof. Jacques Loeb. Brief preliminary reports of investigations will be issued, followed by full reports as the investigations are completed. Numbers will appear at irregular intervals.

AN ENDOWED MEDICAL JOURNAL. — It is announced that a publication to be known as *The Journal of Infectious Diseases* is to appear in the fall under the editorship of Professors Hektoen and Jordan of the University of Chicago. The enterprise is rendered possible by an endowment provided by Mr. and Mrs. Harold McCormick, in memory of their son.

WOMEN PHYSICIANS IN CHICAGO MEDICAL SOCIETY. — Dr. Frances Dickinson and Dr. Rachel H. Carr have recently been elected members of the Board of Councillors of the Chicago Medical Society. This mark of distinction has not hitherto been accorded women in that organization.

KEROSENE DEBAUCH. — *American Medicine* states that according to the police of Philadelphia it is not an unusual thing for boys to become intoxicated by inhaling the fumes from kerosene. The vicinity where these debauchs have been observed is usually in the neighborhood of the railroad yards, where the empty oil cars are stationed. The method of obtaining the fumes is for the boys to climb upon the tank car, place their noses over the manhole and thus inhale the fumes. The effects produced are similar to those produced by alcohol: First, a feeling of exhilaration, then a period of stupor, and following is the period of deep sleep. It is stated that in several instances boys, drunk from these fumes, have been taken to hospitals in the vicinity. From the meager amount of observation in such cases, it is believed that the effects on the system are similar to those produced by alcohol.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 1, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 40, typhoid fever 23, measles 46, smallpox 0.

BOSTON FLOATING HOSPITAL. — The Boston Floating Hospital will make the first trip of the season 1903, July 7. This is a later opening of the work than usual, inasmuch as it is desired to maintain the hospital somewhat later in the fall than has heretofore been done. Fortunately, the weather up to this time has not been such as to demand the care which this hospital provides. It is reported that $11,000 has been received in cash

and pledges for the needed new boat. In the meantime the old one will be fitted up and used as heretofore, although considerably too small for the growing needs of the hospital. As we have hitherto stated, the Floating Hospital will this year be used to test the antitoxin serum for certain intestinal diseases of children. This work will be under the supervision of the Rockefeller foundation and under the direct charge of Arthur I. Kendall, Ph.D., of the Massachusetts Institute of Technology.

REMODELLING OF TENEMENTS. — The opposition at first brought to bear against the Board of Health in its attempt at sanitary reform in the tenement-house districts of Boston has ceased. Vigorous work is now being undertaken in four sections of the city, with the result that buildings previously almost uninhabitable have been made relatively attractive and sanitary. This work, begun under a special act of legislature in 1897, has continued since with decreasing opposition.

NEW YORK.

TETANUS ANTITOXIN AND THE FOURTH OF JULY. — In the latest bulletin of the State Health Department it is announced that the department is prepared to furnish tetanus antitoxin for use in cases resulting from Fourth of July accidents, and the announcement is also made that during the summer the State Antitoxin Laboratory will co-operate with the Rockefeller Institution in an investigation regarding the etiology and treatment of dysentery. Last year, it is stated, there was an outbreak of this disease in the vicinity of Yonkers and Mount Vernon, Westchester County, in which some valuable data were collected by the department.

CONDITION OF ADULT BLIND. — The commission to inquire into the condition of the adult blind in New York State, authorized by the last legislature and appointed by the governor, met in New York on June 25 and effected an organization, with Dr. F. Park Lewis, of Buffalo, as president, and Prof. O. H. Burrill, of Batavia, as secretary.

ANTITOXIN. — The President of the Board of Health has sent to the Mayor, in reply to a communication from the latter, a letter in which he says that the production of diphtheria antitoxin was begun by the department so that physicians might get satisfactory supplies, and also in order that in cases where the family of a patient was too poor to pay for the antitoxin it should be furnished free by the department. Some time after the original arrangement went into effect a provision was inserted in the charter permitting the department to sell its surplus supply. Accordingly the department sold large quantities to persons outside as well as in the city, such sale being due to the confidence felt in the purity of the antitoxin produced by it. It is the express opinion, however, that there are now on the market other products of antitoxin which are of as high grade as that of the New York health department. Believing that the sale of antitoxin to persons outside the city is contrary to the spirit of the charter, he states that he has informed such persons that they must arrange to make their purchases from other producers after July 1. He then suggests that hereafter the department shall disburse all its laboratory products free, as do other municipal and state laboratories, upon receiving the proper requisitions from department officers or private physicians. Such distribution would of course be confined to residents of the city. Should such an arrangement be carried out, between $20,000 and $25,000 annually will have to be furnished by the Board of Estimate and Apportionment, in addition to the present appropriation of about $50,000 for the maintenance of the laboratories.

VERDICT IN FAVOR OF TENEMENT HOUSE DEPARTMENT. — In the Seventh District Municipal Court a jury has returned a verdict in favor of the Tenement House Department, which sought to oblige the owner of a certain tenement house to remove the water-closet accommodations from the yard and place such accommodations on each floor of the house. The defendant's counsel argued that the act is unconstitutional, because it limits the owner's use of his land and premises, and, further, that the change is unnecessary and unreasonable. In approving the jury's verdict the officiating judge expressed the opinion that a citizen has not absolute right over his property, but holds his right subject to control and regulation for the benefit of the public. The rights of property, he said, like other ordinary rights, are subject to such reasonable limits to their enjoyment as will prevent them from being injurious, and to such reasonable restraint and regulation as is established by law. Sanitary experts and builders who testified at the trial stated that there are 9,000 tenement houses in New York which would require similar alterations if this decision is affirmed by the higher courts, and that the average cost would be more than $2,000 for each house. The case will be appealed.

Miscellany.

HARVARD MEDICAL ALUMNI ASSOCIATION.

THE twelfth annual meeting of the Association was held in Boston, on Wednesday, June 24, at 6.30 P.M. There were 151 members present. The following officers were elected:

President, — CHARLES FOLLEN FOLSOM, M.D., 1870, of Boston, Mass.

Ten Vice-Presidents, — JOHN CALVIN WEBSTER, M.D., 1867, of Chicago, Ill.; FREDERICK WILLIAM BORDEN, M.D., 1868, of Ottawa, P. Q.; GEORGE BRUNE SHATTUCK, M.D., 1869, of Boston, Mass.; ERASMUS DARWIN LEAVITT, M.D., 1870, of Butte City, Mont.; BEVERLY MACMONAGLE, M.D., 1876, of San Francisco, Cal.; ISADORE NATHAN BLOOM, M.D., 1881, of Louisville, Ky.; REYNOLD WEBB WILCOX, M.D., 1881, of New York, N. Y.; JOSIAH NEWHALL HALL, M.D., 1882, of Denver, Col.; PERCIVAL JAMES EATON, M.D., 1888, of Pittsburgh, Pa.; EDWARD FITCH CUSHING, M.D., 1888, of Cleveland, Ohio.

Treasurer, — WILLIAM HERBERT PRESCOTT, M.D., 1888, of Boston.

Secretary, — GEORGE SHATTUCK WHITESIDE, M.D., 1897, of Boston.

Assistant Secretary, — JOHN GREENLEAF WHITTIER KNOWLTON, M.D., 1900, of Boston.

Councilors, — (to serve from 1903 to 1907) CLARENCE JOHN BLAKE, M.D., 1865, of Boston; HENRY JACKSON, M.D., 1884, of Boston; MALCOLM STORER, M.D., 1889, of Boston.

The constitution of the association was changed, making it possible to create the office of assistant secretary.

After the meeting the first triennial dinner was held at Westminster Hotel. DR. C. J. BLAKE, president of the association for the last three years, officiated as toastmaster, introducing the speakers very happily.

At the outset he took occasion to say that the project of the new medical department for Harvard University and its new buildings would be the subject for consideration. Referring to what he termed the new era of medical education in this country, he deemed it fortunate to have as a guest one who had both foretold and helped to fulfill the coming of the new movement, introducing Dr. Henry P. Bowditch.

DR. BOWDITCH spoke of the enormous size of the buildings contemplated, due largely to the laboratory method of instruction; he dwelt upon the province of the lecturer, the needs of the elective system, and concluded with the prediction that by the next triennial dinner more definite results may be reported, hoping that in the meantime the buildings would meet with no untoward accidents in the process of their construction.

DR. JOHN COLLINS WARREN was introduced as not only a generous giver to Harvard University, both of his intellectual power and his earnestness, but also as a "generous inciter of others."

Dr. Warren devoted his remarks to an enumeration of the great gifts to the institution, and to the co-operation of the Brigham and other hospitals in the work that Harvard is doing. He also referred to the gift of $225,000 which has recently been made to the Harvard Medical School by one who wishes to remain unknown, and to a gift by Robert Bacon, Esq., of $60,000, to endow a curatorship of the Warren Anatomical Museum, in memory of the late Dr. J. B. S. Jackson.

DR. ARTHUR T. CABOT, in behalf of the Corporation of Harvard University, detailed the clinical advantages made possible, as well as the scientific work that has been going on for years, making itself felt throughout the country and the world. He alluded to the labors of the bacteriologists, the cancer investigation committee, the work of Dr. Councilman in the etiology of smallpox, drawing the conclusion that such work makes this school a specially favorable place for all medical research, and that money devoted in this direction is well spent.

MR. CHARLES A. COOLIDGE, architect of the new buildings, spoke concerning the architectural beauty and practical arrangement of the various laboratories, expressing the hope that by the next triennial dinner the members would see the buildings in a shape to speak for themselves.

PRESIDENT BLAKE'S yielding of the Chair to his successor was graceful in word and manner.

PRES. CHARLES F. FOLSOM reviewed the history of medical instruction in the School, its progress in the struggle against "that failure to grasp the situation, misnamed conservatism," and traced the growth of what he called the Harvard "spirit." While cherishing pride in her traditions, he still felt that there were problems yet to be solved. He deplored the small representation of medical men in the machinery of government of the university, but hoped the day of better things was coming. He thought a lesson could be learned from the Medical School, and because the public seems to approve its work he believed it was a lesson which the college might be wise not to be too late in learning.

LAY ADVICE TO RECENT GRADUATES IN MEDICINE.

IN an editorial in the *Outlook* of June 27 are some timely bits of advice to recent college graduates, one of which is intended for graduates in medicine. It is well worthy of quotation, and we therefore present it in full.

After giving some sound advice to theological students, the writer goes on to say: "Or you are going to practice medicine. If your patients were all reasonable men and women, your task would be easy; but they are not. Even in their best estate they are not all reasonable men and women, and you will have to deal with them when they are not in their best estate, but are morbid. You will have to deal with patients who throw your medicine out of the window, and still expect you to cure them; in one house with a mother busy with other things and careless of the sick child; in another house with a mother whose weak and tearful sympathy does much to negative the influence of your presence and the effect of your medicines. It is not enough for you to know physiology and anatomy and therapeutics; not enough for you to know what your medical school has told you; you must know men and women — their physical constitutions, their mental and moral constitutions. You must understand them — their life, their narrownesses, their prejudices, their unreasonablenesses. You must see into them, that you may minister to them."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 20, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung disease.	Diphtheria and croup.	Diarrheal Diseases.	Scarlet fever.

Deaths reported, 2,860; under five years of age, 963; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 804, acute lung diseases 305, consumption 311, scarlet fever 54, whooping cough 27, cerebrospinal meningitis 3, smallpox 8, erysipelas 5, measles 37, typhoid fever 54, diarrheal diseases 218, diphtheria and croup 82.

From whooping cough, New York 9, Chicago 2, Philadelphia 6, Baltimore 1, Pittsburg 2, Boston 1, Fall River 1, Lowell 1, Lynn 2, Waltham 1, Beverly 1. From erysipelas, Chicago 2, Philadelphia 1, Baltimore 1, Boston 1. From smallpox, Philadelphia 4, Pittsburg 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending June 6, the death-rate was 14.3. Deaths reported, 4,145; acute diseases of the respiratory organs (London) 171, whooping cough 99, diphtheria 38, measles 136, smallpox 6, scarlet fever 40.

The death-rate ranged from 6.4 in Walthamstow to 29.1 in Middlesbrough; London 13.8, West Ham 14.1, Brighton 12.1, Portsmouth 10.7, Southampton 9.0, Plymouth 14.4, Bristol 8.8, Birmingham 14.4, Leicester 10.4, Nottingham 14.2, Bolton 17.7, Manchester 17.8, Salford 14.0, Bradford 13.1, Leeds 12.5, Hull 14.0, Newcastle-on-Tyne 13.6, Cardiff 12.1, Rhondda 17.9, Liverpool 19.9, Hornsey 8.0, Sheffield 18.9.

METEOROLOGICAL RECORD.

For the week ending June 20, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JUNE 27, 1903.

H. E. AMES, medical inspector. Commissioned medical inspector, from Jan. 20, 1903.

C. F. STOKES, surgeon. Detached from the Navy Yard League Island, and ordered to the Bureau of Medicine and Surgery, Navy Department.

C. D. BROWNELL, S. G. EVANS, C. E. RIGGS, M. K. JOHNSON, W. B. GROVE, E. O. HUNTINGTON, surgeons. Commissioned surgeons from March 3, 1903.

H. E. ODELL, passed assistant surgeon. Commissioned passed assistant surgeon from Nov. 8, 1902.

J. J. SNYDER, assistant surgeon. Detached from the Naval Hospital, Philadelphia, Pa., and granted sick leave.

W. W. VERNER, assistant surgeon. Ordered to the Naval Hospital, Philadelphia, Pa.

W. M. WHEELER, L. MORRIS, F. T. PLEADWELL, C. P. KINDLEBERGER and F. C. COOK, surgeons. Commissioned surgeons from March 3, 1903.

G. PICKRELL, surgeon. Detached from the "Iowa" and ordered home to wait orders.

SUBPARIETAL INJURIES OF THE KIDNEY.[1]

BY FRANCIS S. WATSON, M.D., BOSTON.

A PERSONAL experience of six cases of subparietal injury of the kidney has recently led me to make a thorough study of the subject, in the course of which I have collected, formulated and analyzed clinical data to the number of 660 cases, which include all previously published series of importance, all but about 78 individual cases scattered through the literature, these being inaccessible to me at this time, and 25 hitherto unreported, amongst which are the 6 treated by the writer personally.

The investigation has served to confirm or strengthen many of the views of previous writers upon this subject, and has brought to notice certain other features, to which but relatively little attention has hitherto been given. The latter will be considered first; they are as follows:

NATURE OF THE ACCIDENT.

Laceration or serious injury of the kidney may be produced by muscular action alone, and in some instances by what seems a very inadequate degree of force. There are eleven examples of this in the series as well as one of the author's cases.

ELEVEN CASES IN WHICH THE KIDNEY WAS INJURED BY MUSCULAR ACTION ALONE.

(1) *Kellermann.* — A man made a sudden spring backward, felt, in so doing, a violent pain in the left renal region. Hematuria appeared at first urination afterward, and continued for four days, then fever, and a few days later a swelling in the left loin, which increased gradually, was incised on the 18th day, and proved to be a large perinephritic abscess. Drainage. Recovery.

(2) *Hensgen-Siegen.* — A man in lifting a sick woman across a bed felt severe pain in the loin. Hematuria followed at once, and persisted for three days well marked, and for three weeks moderately, the urine then became normal. Expectant treatment. Recovery.

(3) *Same author.* — A seventeen-year old boy lifted a heavy weight. Severe pain in the lumbar region, which was very soon followed by hematuria, the latter persisted, the blood in the urine being abundant all the time, for thirteen days, and subsequently recurred as soon as the patient exerted himself. Treatment expectant. Patient still under observation.

(4) *Franz.* — A man bent the body sharply backward, while carrying a heavy weight. Pain in both kidneys, hematuria — profuse — followed three hours later. This continued for fourteen days, the amount of blood being very large. On the eighth day after the accident he had a chill and a rise of temperature; this was repeated several times during the next twenty-four hours. Expectant treatment. Recovery. The patient was in a critical condition for several days.

(5) A man ruptured his kidney by catching in his arms a heavy sack of meal as it fell from the back of his cart, behind which he was walking.

(6) A man ruptured his kidney by sudden bending forward of the body to avoid striking a burden, which he carried on his shoulders, against a low archway.

(7) A man ruptured his kidney, with *fatal result*, by the muscular effort made in delivering a blow at an opponent with whom he was boxing.

(8) *Campbell.* — A young girl of fourteen in jumping over a hedge, and bending her body sharply forward and to one side in so doing, was seized with violent pain in the loin, fainted and hematuria followed, the amount of blood being abundant, though the duration of the hematuria was short.

(9) *Morris.* — A woman of sixty-six was seized with severe pain in the loin, attending the strain made in lifting a heavy box from shelves. On the following day, fever, rigors and pain resembling renal colic ensued, and persisted without abatement eleven days. Six weeks later — the symptoms still being present though less severe, and loss of weight being marked and progressive — the left kidney was exposed in the loin. On incising the fibrous capsule, two or three teaspoonfuls of bright blood issued from beneath it. The capsule was seen to have been lifted from the kidney by the hemorrhage over an area of moderate extent. The patient made a rapid recovery. (Hematuria not mentioned as having been present.)

(10) *Morris.* — Following a muscular effort, a young woman had a severe attack of pain in the loin, succeeded by a sharp rigor, and hematuria of short duration. During the next six weeks every attempt to get up and go about brought on a recurrence of pain and hematuria. For the last three of the six weeks, the pain became frequent or continuous at night. Frequent urination was present throughout.

Nephrotomy was performed through a lumbar incision eight weeks after the injury. The lower end of the kidney presented an area of dark color, which was found to be softened kidney tissue and effused blood. This was removed, and, together with the nephrotomy wound, was sutured. The patient made rapid recovery and was freed from all symptoms.

(11) The most curious case of all is that reported by Voit, of a woman whose kidney was ruptured by her husband's grasping her forcibly about the waist while waltzing. Severe hematuria promptly ensued, and she suffered at the moment of receiving the injury violent pain in one kidney. Hematuria continued for nearly two months, with occasional intermissions. At the end of this time there were chills, fever and the blood in the urine was replaced by pus. A perinephritic abscess formed, the pus was evacuated a week later by a lumbar incision, and the patient made a good recovery. The kidney was seen at the time of the operation to have been lacerated.

LACERATION OF THE KIDNEY OCCURRING AS THE ONLY RESULT OF BLOWS UPON THE FRONT OF THE ABDOMEN.

In twenty cases of the series, blows or falls upon the front of the abdomen are stated to have been the cause of laceration of the kidney. In all but two of them this was the sole result of the accident. In these two other abdominal organs suffered as

[1] Read before the American Association of Genito-Urinary Surgeons, May 14, 1903, Washington, D. C.

well as the kidney. This does not take into account a considerable number of other cases in which the renal condition was brought about by a crushing force passing over the front of the abdomen while the patients were lying upon the back.

The practical importance of this observation is to warn the surgeon not to be thrown off his guard with respect to injury of the kidney when the accident has been of this character, which might well happen, especially in cases in which hematuria is delayed or absent.

WHEN A SINGLE INTRAPERITONEAL ORGAN IS INJURED IN ASSOCIATION WITH LACERATED KIDNEY, IT IS ALWAYS ON THE SAME SIDE AS THE INJURED KIDNEY.

There is no case reported in the whole series of which the above statement is not true. For example, if the right kidney be injured, the liver, or ascending colon, may be involved in association with it, if there be but a single intraperitoneal organ that has suffered — but never the spleen or the descending colon. When there are multiple intraperitoneal injuries, this rule, of course, has no application. Inasmuch as the latter cases are of very rare occurrence, while injury of a single intraperitoneal organ in connection with laceration of the kidney is relatively frequent, this fact has a practical bearing in those cases in which associated injury of an intraperitoneal organ being suspected, and a laparotomy having disclosed an abdominal cavity filled with blood, no time need be lost in looking for the source of the hemorrhage elsewhere than upon the same side as that of the injured kidney. It also will lead the surgeon to enter the abdomen by an incision on that side, except in the rare instances in which there is uncertainty as to which kidney has been injured, or whether both of them may not have suffered.

In the great majority of instances it is the spleen which is involved in connection with the left kidney, and the liver with the right one; but intraperitoneal hemorrhage comes from the kidney through a rent in the overlying peritoneum, in an even larger number of cases than from either the liver or spleen. The relative frequency of the injury of the different intraperitoneal structures associated with that of the kidney is as follows:

Laceration of the overlying peritoneum, 24 cases; laceration of the liver, 12 cases; laceration of the spleen, 11 cases; laceration of the spleen and liver, 2 cases; mesentery, 3 cases; omentum, 1 case; intestine, 3 cases; total, 56 cases.

THE OCCURRENCE OF ABDOMINAL SYMPTOMS IN CONNECTION WITH THE RENAL INJURY IN THE ABSENCE OF INTRAPERITONEAL LESION.

Symptoms which are usually associated with peritonitis, or intraperitonal lesions, such as distention, tympanites, vomiting, muscular rigidity, etc., occurred in 18 cases, in 8 of which operation demonstrated the absence of any intraperitoneal complication, and in the other 10 the symptoms subsided so rapidly as to make it reasonable to assume the absence of any such complication, or, if it were present, that it was of trivial character. Such symptoms as the above are not infrequently seen in connection with cases of what appear to be abdominal muscular contusions only.

When these symptoms are present in cases of kidney injury complicated by intraperitoneal lesions or laceration of the peritoneum, the following features help to distinguish them from those in which they do not represent such conditions:

In the latter — the *uncomplicated* ones — they usually are most marked immediately or very soon after the accident, are of relatively short duration, and are not progressively severe. In the former, on the contrary, they are progressive, or appear for the first time, or become more marked later in the course of the case. Pain is deeper seated, rigidity and distension are greater, and the former more extended over the whole abdomen when intraperitoneal lesions are present than in the cases in which they are not. The one sure sign by which injury of the peritoneum overlying the kidney, or of intraperitoneal organs when accompanied by hemorrhage, can be recognized, is the presence of free fluid in the peritoneal cavity.

It is to be noted that there is in the series a larger number of cases in which abdominal symptoms *did* represent intraperitoneal complications, than there is in which they did *not*. Furthermore, there are several recorded in which there were *no abdominal symptoms*, although severe, and in a few instances fatal, intraperitoneal lesions were present. The following is an illustrative case of the latter. It is that of a child reported by Wheeler,[2] who was run over by a cart, the wheel passing across the front of the abdomen. An hour or two later it was brought to the hospital and played about upon the floor without showing any evidence of injury for the next hour, at the end of which time there was sudden collapse, and death followed three hours later. Autopsy showed laceration of the right kidney and liver. There was no blood in the urine, which was passed once soon after admission to the hospital.

The *duration* of abdominal symptoms in eight *uncomplicated* cases, and the time of their appearance, was as follows:

Case.	*Time of Appearance.*	*Duration.*
1.	Immediate.	One day.
2.	"	Three days.
3.	"	Five "
4.	End of first day.	Four "
5.	"	Three "
6.	Second day.	Six "
7.	"	Three "
8.	"	Four "

TUMOR.

There are four points with regard to the presence of tumor in the loin to which the writer wishes to call attention, to wit: (1) The relative proportion of the cases in which it represented different conditions in this series. (2) The time of its first appearance with reference to its nature. (3) The increase in its size. (4) Its duration without becoming infected.

(1) The first is shown as follows: There were 111 instances out of the total number of 486 uncomplicated cases, in which tumor of the loin is noted as present. In 39 of them the tumor was

[2] Trans. Royal Acad. of Med., Ireland; vol. xvi, p. 365, 1898.

formed by perirenal extravasation of blood, in 4 hematonephrosis, in 28 traumatic hydronephrosis, in 38 perinephritic abscess, in 2 pyonephrosis.

(2) The time of its first appearance, with reference to its nature, is shown in the following tables: *Thirty-five cases of perirenal hematoma*, or *hematonephrosis ; time of first appearance :* 25, immediate; 1, 12 hours; 1, 1 day; 2, 2 days; 1, 3 days; 2, 7 days; 2, 14 days; 1, 21 days; total, 35 cases.

The last three cases were secondary hemorrhages. With them included, the average time of appearance of the tumor is about two days after the receipt of the injury; excluding them, it becomes about sixteen hours.

Seven cases of traumatic hydronephrosis; first appearance: 1 case, 1 day; 2 cases, 7 days; 2 cases, 28 days; 1 case, 42 days; 1 case, 56 days; total, 7 cases; the average time of first appearance was about twenty-four days.

Twelve cases of perinephritic abscess; first appearance: 1 case, 4th day; 1 case, 5th day; 4 cases, 7th day; 1 case, 8th day; 1 case, 14th day; 2 cases, 28th day; 1 case, 30th day; 1 case, 35th day; average time of first appearance about fifteen days.

From the above it is seen that the majority of tumors which are perirenal hematomas appear immediately or very soon after the accident.

That the average time of first appearance in those in which the tumor represents hydronephrosis is considerably later than in those in which it is perinephritic abscess. The number of cases of the two latter conditions is, however, too small to be of value for such a comparison.

(3) Increase in size of the tumor does not *necessarily* imply dangerous hemorrhage, provided it does not take place rapidly or continue too long. This is shown by four cases in which there was gradual increase in size noted as continuing for periods of between six and twenty-four hours, the patients all recovering under expectant treatment. On the other hand, there were six others in which a more rapid increase in size occurred, accompanied by the general signs of progressive hemorrhage, on account of which operations were performed, laceration of the renal blood vessels being disclosed in four of them, and excessive hemorrhage from the parenchyma of the organ in the other two.

In sixteen cases of perinephritic abscess, *gradual* increase in size of the tumor is reported to have occurred. The same was true in eight of the cases of hydronephrosis.

The nature of the tumor in a considerable number of the instances in which it was perinephritic abscess was indicated by chills and rise of temperature, concurrently with or shortly after its appearance. Chills and fever, however, are mentioned in connection with a number of other cases in which no suppuration took place.

(4) Hydronephrosis and perirenal extravasation may continue to be present for considerable length of time without infection and suppuration occurring. This is seen in four of the former conditions, two of which were present without infection for one month each, and the other two for three months each, while in seven cases of the latter, the duration without infection is reported as fourteen days in two, three weeks in two, twenty-four days in one, and one month in two.

The features of the subject which have been dealt with thus far are, as has been said, such as have received but little attention. Before passing to an analysis of the clinical data with reference to the question of treatment, further details must be considered, which have been more fully discussed by others. These are the following:

FREQUENCY OF SUBPARIETAL INJURY OF THE KIDNEY.

The frequency of the injury may be judged from the following quotations:

Out of 2,610 autopsies made at the Middlesex Hospital between the years 1873 and 1883, there were but 12 in which this condition existed. Goldstein reports 22 cases as the whole number admitted to the Friederichshain Hospital between 1882 and 1902; Waldvogel, 21 from König's clinic at Göttingen between 1895 and 1900; Wyss, 14 from Krönlein's clinic during the past twenty years. At the Boston City Hospital there have been 25 admitted during the last fourteen years.

The relative frequency of injury of the kidney as compared with that to other abdominal organs caused by abdominal contusions is shown by the following table, published by Makins. Traumatic lesions of various abdominal viscera occurred in 89 out of 292 cases of abdominal contusions, in this order of frequency —

	No.		*Per cent.*
Kidney	35	or	39
Intestine	22	,,	23
Liver	15	,,	16
Spleen	10	,,	11
Bladder	4	,,	5
Mesentery	3	,,	3

SUPPOSED MECHANISM BY WHICH THE INJURY IS PRODUCED.

In a relatively small number of cases the kidney is lacerated by direct impact of the ribs, when the latter are fractured immediately over the organ.

Morris quotes Küster to the following effect: "The only theory which satisfactorily explains lacerations of the kidney after non-penetrating wounds is that of hydraulic pressure acting through the full vessels and pelvis, and causing the organ to burst along lines for the most part radiating from the hilus toward the point of maximum impact of the lower ribs, the opposing resistance being supplied by the vertebral column."

"Experiments performed with flaccid kidneys thrown with some force upon the floor showed that only superficial laceration was thus produced."

"On the other hand, when the pelvis and arteries were injected and ligatured after closure of the vein, and the organ thrown down, there ensued deep laceration of the kidney substance."

The majority of rents found in subparietal renal injuries are in the direction of the transverse axis, and are most marked near the middle of the organ, which is its narrowest and weakest part. A great many different forms of wounds, however, are met with.

The ability of the kidney to maintain a useful

degree of functional capacity, and also a remarkable power of regeneration of its tissues after severe traumatisms, has been shown by numerous experiments, as well as clinical and postmortem observations. The readiness with which the healing of wounds of the organ occurs has often been noted.

Among the more recent experiments with reference to some of the above points, those of Dolgoff are appropriate in this connection. "Dolgoff found that severe laceration of the kidneys of dogs, even the tearing of them in halves, did not result fatally. Also that the animals survived the removal of the cortical portion of one kidney, and of half of the cortex of the other, provided it was done gradually and at intervals, but if done simultaneously, death followed speedily.

Wounds of the medullary portion were graver in their consequences than those of the cortex. Simultaneous injury of one half of the medullary portion of both the organs was always fatal.

If one kidney was removed, injury of the medullary portion or cortex of the other killed the animal slowly.

Wounds of the kidney healed more readily and rapidly if the capsule was preserved, and especially if its cut edges were united.

The renal tissue remaining after removal or injury of parts of it showed great regenerative power.

The urine of animals with wounded kidneys showed albumen and an excess of uric acid."

HEMORRHAGE.

Hemorrhage occurs as: (1) Hematuria; (2) perirenal; (3) intrarenal (hematonephrosis, or subcapsular); (4) intraperitoneal.

HEMATURIA.

This is the most constant and, of course, the most characteristic symptom of the renal injury. That it does not alone, if in moderate degree, warrant the diagnosis of laceration of the organ, is shown by such well-known examples as those of individuals who have attacks of it after riding a hard-gaited horse. It has not infrequently been observed as the result of manipulation of the kidney by physicians when examining patients.

In patients having renal calculus or malignant disease of the kidney, and in those who are subject to attacks of paroxysmal hematuria, it would naturally be liable to occur in connection with injuries without necessarily implying that the kidney was lacerated. In the absence of any of the above conditions, hematuria, if the quantity of blood be at all large in the urine, is presumptive evidence of the existence of laceration of greater or less extent, and if a tumor in the loin is present as well, the diagnosis is, practically speaking, certain. Hematuria is present in at least 80% of all cases.

Absence or delay in its appearance occur in a small proportion of instances. In 340 of the cases of this series hematuria was absent in 7; delayed in 11 and intermittent in 6 of them.

The *time of appearance of hematuria* after the accident was noted in 117 cases. In 106 of them it was seen in the first passage of urine; in 11 it was delayed, for varying periods between 12 hours and 5 days.

The *delay* in the appearance of hematuria, if not long, is sometimes referable to thrombus formation, and the subsequent dislodgment thereof, in other instances to obstruction of the ureter. *Absence* of hematuria is due to one of the following causes: Tearing across of the renal pelvis, ureter or blood vessels; disintegration of the kidney, or obstruction of the outlet of the renal pelvis.

DURATION OF HEMATURIA.

The average duration of hematuria in 167 cases in which the time was noted was 8 days. The longest durations were reported in 7, as follows: 56 days, 46 days, 42 days, 28 days, 21 days, 21 days, 18 days.

In none of the instances of long duration was the amount of blood in the urine abundant at any one time.

PERIRENAL HEMORRHAGE.

Perirenal hemorrhage takes place from the renal parenchyma, the fibrous capsule being ruptured and allowing the blood to make its exit through the rent, from the renal blood vessels when they are injured, or from the numerous small vessels of the perirenal fat tissue.

It manifests itself by an area of percussion dullness, or the formation of a tumor in the loin, of greater or less extent according to the amount of blood poured out. If very abundant the constitutional signs of progressive hemorrhage become evident, and the tumor increases rapidly in size. These symptoms are most conspicuous in connection with injury to the renal vessels. *Spontaneous arrest* of such bleeding, even in the latter case, is, however, sometimes seen. In one case — Guinard's,[3] — which was operated upon the eighteenth day there had been a laceration of the renal artery, and yet the amount of blood which had been poured out into the perirenal tissues had not been sufficient to endanger the life of the patient.

The spontaneous arrest is due in part to the pressure exercised upon the growing hematoma by the overlying peritoneum when the latter is firmly attached. When, on the contrary, it is relaxed, as it not infrequently is, the only restraint to continued hemorrhage is from thrombus formation. This occurs quickly enough in some instances to avert immediate danger. Occasionally the thrombus becomes dislodged and gives rise to secondary hemorrhage, which is apt to be more serious than the primary one.

The hematoma formed around the kidney and behind the peritoneum pushes the latter forward, and may attain very large size. The writer in one of his cases found a blood clot extending from the diaphragm to the border of the pelvis, pushing the peritoneum far forward into the abdominal cavity. In this case the renal vein had been torn across.

When the capsule is not torn, the blood from the renal parenchyma may coagulate within the pelvis and (or) beneath the capsule, blocking the orifice of the ureter, distending the pelvis enormously, interfering with the urinary function and the circulation of the blood, producing a great enlargement of the organ by the latter, and dissecting the fibrous capsule from its surface. When this occurs, it is

[3] Rev. de Chir., 1897.

announced by the sudden cessation of hematuria, appearance or increase in size of a tumor in the loin, and accession of pain.

Hemorrhage may arise from the vessels of the perinephritic fat tissue *alone*, or in connection with intrarenal bleeding, no laceration of the kidney being present. This occurred in one of the writer's cases. When there is no intrarenal bleeding, that which occurs from the perinephritic fat blood vessels, if sufficiently abundant, which it rarely is, shows itself as a tumor in the loin, and hematuria will be absent.

Intraperitoneal hemorrhage arising from the kidney involves the necessary existence of a rent in the peritoneum overlying it.

There were 20 cases in the whole series in which intraperitoneal hemorrhage proceeded from the kidney or its blood vessels, and through a laceration in the peritoneum. In none were there associated intraperitoneal lesions; in 16 of them the renal blood vessels were torn.

RUPTURE OF THE RENAL BLOOD VESSELS.

In addition to these 16 there were 4 others in which the renal blood vessels were injured, but the peritoneum was not torn, the hemorrhage being retroperitoneal. Both vessels were torn in 3 cases; the artery alone in 1, and the vein alone in the remaining 14 — altogether 20 cases in which the renal blood vessels were involved.

Aneurysm of the renal vessels may result in these cases (Morris has collected 19 examples of this condition) and give rise to serious or fatal hemorrhage, sometimes at remote periods after the original injury.

SUPPURATION.

Suppuration occurs as perinephritic abscess, pyonephrosis, suppurative nephritis, purulent peritonitis.

Its frequency is variously estimated in the series published by different writers. Grawitz found 22 instances of suppuration in 90 cases. Küster reports it as having been fatal in 27 out of a total of 222 uncomplicated cases. Out of 486 uncomplicated cases of the present series it is noted in 68, in which it appeared in the following forms: Pyonephrosis, 6; suppurative nephritis, 4; purulent peritonitis, 9; perinephritic abscess, 38; not stated, 11; total, 68.

The infection which results in suppuration is invited by the open door afforded by the wounded organ, and may take place through the blood channels, from the bladder or from the intestine. The experiments of Delbet are interesting in this connection. He produced infection of an injured kidney by injecting immediately previous to crushing the organ 1 cc. of a solution containing 1 drop of a virulent culture of the bacillus commune coli to 10 cc. of fluid. The animals — rabbits — died shortly afterward. Rich colonies of the bacillus commune coli were found both in the renal parenchyma and the perirenal tissue. In control animals with sound kidneys this was not the case.

The relative rarity of ascending infection from the bladder in cases of traumatic hydronephrosis, as compared with the more frequent infections that occur in perirenal extravasations, strengthens the view that the route of bacterial invasion is more often through the blood current or from the intestinal tract, in the case of the latter, than from the bladder.

CAUSES OF DEATH.

It is from the uncomplicated cases alone that an accurate estimate of the mortality can be derived. The complicated cases have been included, however, in the study, but are considered separately. Cases having lacerations of the peritoneum are classed with those having intraperitoneal lesions among the complicated ones.

HEMORRHAGE.

The most fatal factor in subparietal laceration of the kidney is hemorrhage.

It was responsible for 25 deaths out of the total number of 112 *uncomplicated* cases which ended fatally. The nature of the hemorrhage in these 25 fatal cases was as follows: Hematuria in 8 (in 7 of them it was secondary); in 12 perirenal extravasation of blood (4 of them having the renal vessels torn, and in 8 the blood proceeding from the renal parenchyma). In 4 there was secondary hemorrhage, the source of which was not specified; in 1 the hemorrhage is termed intrarenal.

COMPLICATED CASES.

Laceration of the peritoneum or intraperitoneal organs is the most fatal complication of ruptured kidney. Death is due in the larger number of such cases to intraperitoneal hemorrhage, as is seen by the following figures: The total number of cases with these complications was 62; the total number of deaths was 48. Of these 48, intraperitoneal hemorrhage caused death in 36, or a little more than 66% of the deaths in this class of cases.

Altogether, therefore, 61 of the entire number of 190 deaths which occurred in both complicated and uncomplicated cases were due to hemorrhage.

SUPPURATION.

Twenty-five of the 112 deaths of the 486 uncomplicated cases were due to suppuration, as follows: Perinephritic abscess, 21; septic infection and abscess, 1; pyonephrosis, 2; suppurative nephritis, 1; total, 25.

ANURIA.

Anuria caused death in ten of the series, in which but one kidney was injured, and the other was normal. In several others death resulted from laceration of both kidneys, and in four there was but one kidney. Anuria occurred in the latter and in some of the former, but was not the immediate cause of death, shock or hemorrhage being the more direct agents in this respect.

Anuria of twenty-four or forty-eight hours' duration was present in several cases, which ended in recovery, or in which the renal function was restored before death resulted from some other cause. Butler records an instance of anuria lasting thirteen days before the patient died; the other kidney was atrophied, and the ureter of the injured one obstructed by a mass of débris.

Morris quotes an example of intermittent anuria reported by Cerou which was, he thinks, explained

by the formation of an aneurism of a large branch of the renal artery within the capsule of the kidney.

When of short duration, and recovery takes place, anuria is to be referred, so far as we can judge, to reflex inhibitory action upon the other kidney, because of injury to its mate, the latter's function being temporarily suppressed by the traumatism, or by injury to its pelvis or ureter, or by obstruction of the latter by clot or débris. If of longer duration than 36 or 48 hours, anuria is generally of grave significance.

PERITONITIS.

There were nine deaths referable to peritonitis in the *uncomplicated* cases, and five in those having *injuries of the abdominal organs associated* with that of the kidney.

Numerous experiments have been made with animals, and a considerable number of clinical observations are also available for the purpose of determining the effect of the presence of urine, or urine and blood, in the peritoneal cavity. Quervain [4] has written one of the most recent and useful articles upon this subject, in the course of which he summarizes the opinions and observations of a number of different writers, some of which are of interest in this connection.

Quervain quotes the following authors as holding the opinion that except for such aid as can be derived from surgical intervention, all patients into whose peritoneal cavity urine and blood are extravasated die of septic peritonitis — Küster, König, Albarran, Schede, Petroff, Edler. Grawitz, on the other hand, as far back as 1888, asserted that the danger from laceration of the peritoneum in cases of subcutaneous rupture of the kidney was owing to the free exit afforded for the blood into the peritoneal cavity, and denied that the presence of urine there was necessarily of serious consequence.

Tuffier had already demonstrated by experiments on animals that no urine flows from the surfaces of lacerated renal wounds, and that in order to have urinary extravasation in such circumstances the renal pelvis, or one of the calyces, must stand in communication with the renal surface through the wound. Also from another series of observations that the introduction of urine into the peritoneal cavity, provided it was made gradually once, or even repeatedly, if only intervals of sufficient length were made between the different introductions, did not cause peritonitis, whereas if the flow was continuous, the contrary was the case.

Israel and Grawitz found that urine which flowed into the peritoneal cavity from a divided ureter in the case of dogs did not kill them sooner than four or five weeks.

Quervain's experiments in the same direction yielded similar results, and showed further that the peritoneum very quickly protected itself from the encroachments of the extravasated fluids, by formation of adhesions. When these failed, steady flow of urine into the peritoneal cavity usually resulted in peritonitis.

TREATMENT.

An important influence upon the mortality being exercised by the method of treatment adopted, the following analysis with reference to this aspect of the subject has been made as a basis for comparison of the various methods and for the study of such other details as are of importance and interest before considering the special features of the treatment.

The largest series of cases hitherto published is that of Delbet of 320. When comparing methods of treatment he divided them into three classes: (1) Cases treated expectantly. (2) Cases treated by operations other than nephrectomy. (3) Cases treated by nephrectomy.

For the sake of convenience the writer has adopted the same classification, but has carried the analysis of the whole number of the series, including Delbet's cases, further than was done by him.

The author has studied the details of all the cases included in this analysis, so far as the reports of them permit, has let the figures tell their own story for what it is worth, and has not changed or transferred any of the data, or made any suppositions of what would probably have shown different results from those which appear, had something happened other than that which did actually occur. Moreover he does not think that a statistical compilation such as that which is about to be presented forms a sufficient basis for making final conclusions, and that the exercise of sound surgical sense, in dealing with individual cases, is more valuable than what may or may not be shown in a general way by the figures of such a statistical calculation, even though it be made with more than twice the number of data hitherto gathered together for purposes of analysis.

ANALYSIS OF CASES WITH REFERENCE TO TREATMENT, CAUSES OF DEATH, ETC.

	Cases.	*Deaths.*
Total number available for this purpose	603	191, or 31%
Total number without associated injuries	487	113, or 23%
Total number with associated injuries	116	78, or 67%
	603	191

The 487 uncomplicated cases classified with reference to method of treatment are as follows:

	Cases.	*Deaths.*	*Mort'ty.*
Treated expectantly	273	81	27%
Treated by operations other than nephrectomy	99	7	7%
Treated by nephrectomy	115	25	25%
	487	113	

UNCOMPLICATED CASES TREATED EXPECTANTLY.

Causes of death in 56 of the 81 fatal cases treated expectantly.

Perinephritic abscess	17
Pyonephrosis	1
Hemorrhage (hematuria in 8, perirenal in 7; in 3 of the latter the renal vessels were torn)	15
Anuria	10
Peritonitis	5
Shock	4
Uremia (absence of other kidney in two of them)	4
	56

Of the 25 other deaths the cause is not stated.

[4] Deutsche Zeitschr. f. Chir., vol. 62, 1901-02, p. 58.

NINETY-NINE UNCOMPLICATED CASES TREATED BY OPERATIONS OTHER THAN NEPHRECTOMY.

Treated by lumbar incision, tampon and drainage.	*Cases.*		*Deaths.*		*Mort'ty.*

	14	14	1	1	
Cases treated by lumbar nephrotomy.					
Intrarenal hemorrhage or suppuration. (The two fatal cases had the other kidney injured also.)	11	11	2	2	
Laceration and hemorrhage.					
Treated by laparotomy and drainage	11	11	1	1	
Treated by lumbar incision and suture of the renal wound	8	8	0	0	
Treated by partial nephrectomy	2	2	0	0	
Totals,	99			7	7%

COMPLICATED CASES TREATED EXPECTANTLY.

Total number, 56; deaths, 51; mortality, 91%.

Conditions and causes of death in 46 fatal cases.

Anuria (absence of one kidney, 2; both kidneys injured, 2)	9
Injury to lung or other pulmonary complications	8
Dislocation of the neck	1
Fractures (3 of skull, 5 multiple)	8
Rupture of bladder	1
	27

Intraperitoneal.

Associated injuries, 24; deaths, 24; mortality, 100%.

Intraperitoneal hemorrhage through torn peritoneum	9
Laceration of liver (shock and hemorrhage)	5
" " spleen (shock and hemorrhage)	6
" " small intestine (peritonitis)	2
" " mesocolon (peritonitis)	1
" " mesentery (hemorrhage)	1
	24
Total,	51

COMPLICATED CASES TREATED BY OPERATIONS OTHER THAN NEPHRECTOMY.

	Cases.	*Deaths.*	*Mort'ty.*
Laceration of the peritoneum	5	3	
Three treated by lumbar incision and drainage, 1 of these three died from hemorrhage.			
Two treated by laparotomy, tampon and drainage, and both of them died, one from peritonitis, one from hemorrhage.			
Laceration of liver and peritoneum	4	1	
Three treated by laparotomy, tampon and drainage, one of these died from hemorrhage.			
One treated by laparotomy, suture of liver, tampon of renal wound and drainage. This patient lived.			
Laceration of spleen and peritoneum	4	2	
Two were treated by laparotomy and splenectomy, the kidney not being touched. Both recovered.			
Two treated by laparotomy and tamponing the spleen. Both died, one from hemorrhage, one from peritonitis.			
Laceration of mesentery	1	1	
Treated by laparotomy, ligation of injured vessels of mesentery, tampon of kidney. Death from peritonitis.			
Contusion of descending colon	1	0	
Treated by suture of the injured bowel.	15	7	46%

ANALYSIS OF CASES TREATED BY NEPHRECTOMY.

	Cases.	*Deaths.*	*Mortality.*
Total number	160	44	27.5—
Uncomplicated cases	115	25	21—
Complicated cases	45	19	42—

Abdominal "	44	14	30—

Lumbar nephrectomies.

	Cases.	*Deaths.*	*Mortality.*
Primary uncomplicated	42	12	30—
Secondary uncomplicated	22	3	14—

Causes of death in the 12 fatal cases of primary uncomplicated lumbar operation:

Hemorrhage and shock in 10, peritonitis in 1, infection and sepsis in 1, (the renal vessels were torn in 3 of the 10 fatal cases from hemorrhage.)

Causes of death in the 3 fatal cases of secondary uncomplicated lumbar operation:

One from shock attending operation; 2 from sepsis.

	Cases.	*Deaths.*	*Mortality.*
Primary lumbar complicated	5	3	
Secondary lumbar complicated	6	4	
	11	7	

Causes of death in the 3 fatal primary operations:

The peritoneum was torn in all of the 3 fatal cases. In one of them the intestine, which was adherent to the peritoneum overlying the kidney, was torn. Gangrene and septic peritonitis were the causes of death in this case. In the other two the peritoneum was torn also, and intraperitoneal hemorrhage and shock caused death.

Death in the 4 fatal secondary operations was due to:

Peritonitis in 2; in both the peritoneum was torn. In 2 to sepsis, 1 following suppuration in the form of subphrenic abscess and purulent pleurisy, and 1 perinephritic suppuration of long duration.

ABDOMINAL NEPHRECTOMIES.

	Cases.	*Deaths.*	*Mort'ty.*
Total number	44	14	30%
Uncomplicated	11	2	18%
Complicated	33	12	36%

	Cases.	*Deaths.*
Primary uncomplicated	6	1 (hemorr'ge and shock)
Second'y uncomplicated	5	1 (peritonitis)

	Cases.	*Deaths.*
Primary complicated	30	10
Secondary complicated	3	2
	33	12

Causes of death in the 10 primary complicated cases were as follows: Hemorrhage from ruptured spleen in 2, intraperitoneal hemorrhage from the kidney in 3, hemorrhage from liver and spleen in 1, shock attending splenectomy and nephrectomy in 2, peritonitis in 1, pneumonia in 1.

Causes of death in the 2 fatal secondary operations were: Hemorrhage and shock attending resection of intestine and nephrectomy in 1, shock and anuria — both kidneys being injured — in 1.

(To be continued.)

A CASE OF ACUTE EPIDIDYMITIS IN AN UNDESCENDED TESTICLE, WITH GONOCOCCI DEMONSTRATED IN THE EXCISED ORGAN.

BY FRED T. MURPHY, M.D., BOSTON.

From the Clinico-Pathological Laboratory of the Massachusetts General Hospital.

AN acute inflammation in an undescended testicle demanding operation is not remarkable. The demonstration of gonococci in the organ thus removed is unique, so far as I can learn.

Since 1892, when Eraud [1] published his observations on the etiology of acute epididymitis, and concluded that the toxin obtained by him from a micro-organism cultivated from the urethra was the cause, the bacteriology has been much discussed. Soon after this publication d'Arlhac [2] substantiated these conclusions by growths on culture media and animal experiments. He isolated this diplococcus, similar in size and staining properties to the gonococcus, but growing freely on ordinary culture media, and called it the orchicoccus. Eraud and Hugounenq [3] were able to prove to their own satisfaction that the orchicoccus was distinct from the gonococcus, that it was the cause of epididymitis, but that it might be present in the urethra without exciting such an inflammation. Somewhat later Carpentier [4] recognized this special organism as an active irritant in epididymitis, and Rollet [5] believed it to be the sole cause of the inflammation. While these observers uniformly found the growth on culture media to differ from the gonococcus, yet their conclusions have not been received without question, and the orchicoccus as described has not been accepted as a definite organism. Based on the large number of negative and the small number of positive results, a theory of irritation from a gonococcus toxin was advanced, but it lacks experimental proof. When the difficulty of cultivation of the gonococcus is considered, these negative results are not noteworthy. As is illustrated by the case of Collan,[6] the immediate negative report from cover-glass preparations may prevent further investigation. Here a swelling of the epididymis was aspirated, but only serous fluid withdrawn, which was negative in the stained specimen, but on proper culture media gave an abundant growth of pure gonococci. Also the slight tendency of the gonococcus to cause frank suppuration is well recognized, and without an abscess, or some rare complication, as in the case to be reported, the opportunities of obtaining material for examination are few. Organisms other than the gonococcus have been isolated from an abscess of the epididymis by Jadassohn,[7] staphylococcus, and Macaigne and Vauverts,[8] Friedländer's bacillus; so that the possibility of a mixed infection cannot be denied. With our present acceptance of the gonococcus, however, as the cause of acute urethritis, and the not uncommon association of the epididymis with unusual irritation, as in irrigation of the posterior urethra or massage of the seminal vesicles, the probability of its being the etiological factor must be allowed. The increasing number of cases in which the gonococcus has been demonstrated also confirms the opinion that it is the specific organism of acute epididymitis, though inflammation with trauma, circulatory disturbances, as was held by Porosz,[9] and a mixed infection are possible causes. Routier,[10] in July, 1895, reported gonococci in the pus from an abscess of the epididymis, but gave no data other than a microscopic examination of a Gram decolorizing diplococcus. Grosz,[11] in November, 1897, gave the first complete report of a positive growth of gonococci obtained from the pus from an abscess of the epididymis. His observations were complete and the growth on cultures was positive. In the next month Collan reported the case cited above, in which only serous fluid was aspirated from a swelling of the epididymis. Since that time cases have been reported with careful examinations of culture growths by Harttung,[12] Colombi,[13] Witte,[14] Reach,[15] Pizzini [16] and Karwowski.[17] All cultures were obtained from isolated abscesses in the epididymis except in the case of Colombi, which in addition had a general infection. Laurent [18] notes a case in which the gonococcus was identified by form and color reaction from smears from the epididymis, but no cultures were made.

The case which I have to present entered the Massachusetts General Hospital on August 9, 1901, on the service of Dr. S. J. Mixter. He was seen by Dr. G. W. W. Brewster, and I have these gentlemen to thank for the opportunity of operating on and reporting the case.

J. B., twenty years old: single; clerk. On the afternoon of August 9, patient was admitted to the accident room with the diagnosis of strangulated inguinal hernia.

Previous history unimportant except that the left testicle had never been in the scrotum, and five weeks before he had contracted his first gonorrhea. Treatment had been by internal remedies, and for some days the urethral discharge had been practically absent. No acute symptoms until the morning of the day before entrance, when he noticed a small lump in the left groin which was exceedingly tender and painful. During the last twenty-four hours pain and tenderness increased. Bowels moved on the morning of the 9th. No vomiting. Examination showed a fairly developed and nourished man, who seemed moderately sick. Temperature, 102.4; pulse, 108; respiration, 26; white count, 18,000; heart, no murmurs; pulse, of fair strength; lungs, negative; belly, soft, not distended; right testicle in the scrotum and of normal size; left testicle absent; penis free from scars; no urethral discharge could be expressed. In either groin were slightly enlarged glands. On the left side just above Poupart's ligament and external to the external ring was a tender tumor, the size of the end of the first finger, over which the skin was reddened. It was apparently distinct from the chain of glands, dull on percussion, and gave no impulse on cough. The external inguinal ring was plugged with a mass which seemed to extend on the external oblique fascia to the tumor. Right inguinal canal normal.

Diagnosis made of acute inflammation of an undescended testicle, and the patient sent to the ward with an ice bag on the groin. In the ward he seemed to grow more acutely sick and suffered great pain. No vomiting, and belly unchanged. At 8 P.M. the temperature had risen to 104.2 and the pulse was of poorer quality. Operation was

advised, and the patient consented to the loss of the testicle if necessary.

Operation with general anesthesia. The incision was made over the tumor as for hernia. Carrying the dissection through the skin, the subcutaneous tissue was found very edematous. Lying on the external oblique fascia about one cm. outside of the ring was what appeared to be a small testis. An enlarged and porky cord extended from this, and at the external ring was acutely flexed. The testicle was atrophied to such an extent and the cord so short that no attempt to replace it in the scrotum was made. The external oblique fascia was split to the internal ring. Then the indurated cord was tied off as high as possible with catgut and the fascia caught together with interrupted stitches of the same material, a small gauze drain being left in the inguinal canal. Skin closed in the usual way. Dry dressing. After the operation the patient had a very comfortable night, and by morning the temperature had dropped to normal, with the disappearance of all symptoms. The wick was removed on the second day, and the wound healed practically by first intention. Patient was discharged on the eighteenth day.

The specimen removed at operation was examined by Dr. James H. Wright of the clinico-pathological laboratory of the hospital, and his report is as follows:

The specimen sent for examination consists of an epididymis without any apparent testicular substance. It is surrounded by what appears to be a thickened tunica vaginalis. Perhaps 1.5 cm. of spermatic cord is present. On longitudinal sections made through the epididymis, the interstitial tissue appears to be increased in amount and the color of the cut surface is dark red with a number of grayish walled tubules showing, which are filled with a yellowish semi-solid material or with thick opaque white fluid.

Microscopical examination of cover-glass preparations from the material in the tubules, stained by Gram's method and afterwards with Bismarck brown, shows a small number of brown-stained diplococci, like gonococci in size and shape, situated both within and outside of the pus cells, which are numerous. In cultures on hydrocele agar from the contents of the tubules above described there developed a variable number of colonies, grayish white and pearly in appearance, and of rounded outline, the larger of which attained a diameter of about 2 mm. after about forty-eight hours in the incubater. These were composed of Gram decolorizing diplococci, sometimes appearing as tetrads and resembling gonococci. Further study of these cocci in subcultures resulted as follows: They do not grow upon plain agar (reaction + 1.7). In one tube, upon which a considerable quantity of material was sown, two or three colonies developed, but several other plain agar tubes inoculated parallel with the hydrocele agar cultures showed no growth after forty-eight hours. The colonies on the hydrocele agar appear as rounded, translucent, pearly disks attaining the diameter of about 2 mm. in some instances.

On dry hydrocele agar the growth has a viscid consistency, stringing out when touched with a platinum needle. Under a low magnifying power the colonies appear as translucent disks with smooth, rounded outlines, showing in their central portions small brownish granular masses irregularly distributed. The coccus decolorizes by Gram, and shows a tendency to grow in the form of tetrads. In a culture about forty-eight hours old the cocci show marked involution forms and degeneration. The organism in this case is clearly the gonococcus.

Microscopical examination of hardened sections taken from different places in the specimen shows the larger tubules to be filled with pus, while some of the smaller tubules are not so affected. The epithelium of the tubules containing pus is for the most part absent, and there is in some instances purulent infiltration and degeneration of the surrounding tissue. In some tubules diplococci like gonococci are present inside the pus cells. The interstitial issue shows marked infiltration with fibrin, and moderate infiltration with leucocytes and other inflammatory cells.

The blood vessels are dilated and gorged with red blood cells.

In cross section of the spermatic cord, the lumen of the vas deferens contains pus and the epithelium lining it is absent and disintegrated. In the pus, diplococci like gonococci are observed in small numbers. There is some infiltration of the substance of the cord with inflammatory cells together with fibrin. No proper testicular substance is apparent in the sections.

We have to do, then, with a case of epididymitis without abscess formation, the usual clinical condition. The gonococcus clearly was the infecting agent in this case, and it seems to me that the only reasonable ground to take is that it is the micro-organism concerned in all cases of epididymitis with gonorrheal urethritis, possibly rarely associated with a mixed infection. Why the smaller tubules were not generally involved it is hard to explain unless they represent more distant portions of the vasa efferentia beyond the limits of the process. This specimen must, I think, add materially to the evidence that epididymitis is due to the presence of the gonococcus in the epididymis, and is not due to the absorption of toxin from the urethra or to the primary infection of other micro-organisms. Clinically the differentiation from the other possibilities of acute inflammation, as adenitis, incarcerated or partially strangulated hernia, is not without interest.

THE NERNST LAMP FOR THE PRODUCTION OF ETHER WAVES FOR USE IN THERAPEUTICS.

BY WILLIAM ROLLINS, BOSTON.

ETHER waves from two forms of electric lamps are now used extensively in therapeutics in Europe and to a less extent in America. Where short ether waves are required the arc is the more suitable, as the temperature is higher, making the proportion of short waves greater; and having no glass covering like the incandescent lamp there is no absorption from this source. Glass absorbs practically all the

waves shorter than 300 uu., as does the atmosphere those given out by the sun. During the past year I have made experiments with Prof. Walter Nernst's lamp, in which a rod containing a preparation of zirconia is heated by an electric current. This like the arc requires no glass covering, though it is supplied with one. Loss of short waves is therefore avoided. The light is well suited for use in therapeutic cabinets in which an even distribution of radiant energy is desired and obtained by using many incandescent bulbs — over ninety in one of Dr. Kellogg's. A second advantage over incandescent bulbs is that the consumption of current for the same number of light waves is greater, less of the current being converted into the longer heat waves. I do not expect the Nernst lamp will supersede the older forms for therapeutic purposes, but it is certain to have a place of its own. Ether waves are now so much used in medicine that it seems desirable to have some general term under which all the forms, such as x-light, ultra violet light, actinic light, ordinary white light, red light, heat and electric waves, can be grouped. I am in the habit of using the term "ether therapeutics" for this purpose, and suggest it to others as a broad though definite term.

Clinical Department.

A CASE OF MALIGNANT ENDOCARDITIS WITH MENINGITIS, PNEUMOCOCCUS INFECTION.

BY L. C. MILLER, M. D., WORCESTER, MASS.

In spite of Broadbent's protest against the use of the term "malignant," as applied to endocarditis instead of "infective," I have preferred it in this case for the reason that it illustrates the fact that malignant endocarditis is usually fatal.

REPORT OF CASE.

Mrs. W., sixty-one years old, widow, hospital matron.

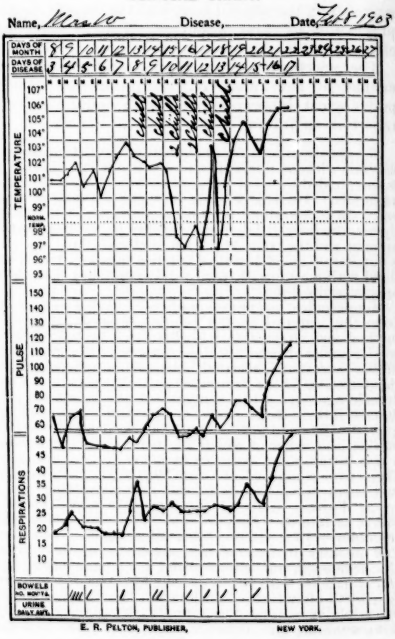
Family history. — Father killed in accident; mother died of consumption; brother of Bright's disease.

Previous history. — She has had more or less articular rheumatism for years. Last spring she had what was called "grippe," accompanied by a nasal discharge. She never permitted an examination of the nose, but Dr. Getchell, from her description of the symptoms, considered that she had disease of either the frontal or ethmoidal sinuses, probably the frontal.

During the above illness a soft systolic murmur was found at the apex of the heart, and a mitral lesion diagnosed.

Recently she has complained of trouble in her head. Some time (a week or two) before her present illness she fell on the ice and struck her head a severe blow. At about the same time, whether before or after it is impossible to determine, she had an attack of dizziness, followed by confusion of mind resembling aphasia. This lasted five or six hours. About four weeks before death she nearly fainted in church.

Present illness. — Feb. 6, about midnight, she had a severe chill, with nausea and retching but no vomiting. The remainder of the night she had chills or chilly sensations. The next morning she felt some nausea. The temperature was not taken.



For three days she remained in bed without improvement.

I saw her first Feb. 9. She complained of a cough and of some mental confusion (feeling stupid, and not being able to finish a sentence). She did not complain of pain or refer her illness to any particular part of her body.

She seemed cheerful, laughed and joked as was her wont, but was evidently anxious about herself. She looked whiter than usual.

Physical examination. — The joints of her hands were much enlarged and thickened. Her pulse was 70', full and regular; the radial arteries slightly atheromatous. (Her pulse was normally from 50' to 55'.) Respiration 20', regular and easy.

CLINICAL CHART.

Chest, lungs. — The right side was negative. On left side, below, especially behind, there was a slight dullness with slightly diminished respiratory sounds.

Heart. — The apex beat was felt in the fifth interspace in the mammary line. Percussion showed no enlargement of the cardiac area. There was a soft systolic murmur, most marked at the apex, much less so at the base. Accentuation of the pulmonic second sound was doubtful. The aortic second sound was more accentuated than the patient's age would account for. The systolic mur-

mur was easily heard in the axilla and behind near the angle of the scapula.

Abdomen. — The spleen was not felt. There were no unusual symptoms found in the abdomen. Its walls were very thick and made the palpation of the liver and spleen practically impossible.

There was no edema anywhere. The pupils were equal and responded to light.

The urine examination of the previous day showed: Urine strongly acid; specific gravity, 1.030; albumin trace; sugar 0; urea 3.8%; sediment, a few brown granular casts, a few red blood corpuscles, a moderate number of leucocytes, amorphous urates.

In all, eight examinations of the urine were made. The highest specific gravity was 1.030, lowest 1.018. Only a faint trace of albumin was ever found. The urea never over 3.8%, the lowest being 1.9%. In the sediment were always hyaline casts, leucocytes, uric acid crystals, and epithelium; sometimes granular casts; once a waxy cast.

The blood count showed 15,000 leucocytes at the first count and 16,000 at the second count.

No diagnosis was made after this examination.

The bowels were sluggish, but responded to a compound cathartic pill. Strychnia and small doses of whiskey were ordered. The stomach symptoms had quieted down and milk with plain soda was advised.

The next day, the fifth day of the sickness, the patient seemed much the same. The left lung seemed duller on percussion and the respiratory sounds more diminished. The temperature had fallen to 99.8° in the morning, but went up to 101° by mid-afternoon. The pulse was 54′ and 50′. The respirations 22′ and 20′.

The sixth day of the illness the patient showed more anxiety about herself. She complained that she could not finish a sentence and felt stupid. The highest temperature was 101.8°, the lowest 99.2°; pulse, highest 54′, lowest 50′. The bowels moved after a compound cathartic pill. Examination of the chest showed less dullness and clearer respiratory sounds, and by the eighth day the lungs were negative.

The eighth day she had a chill lasting ten minutes. The temperature went from 98.6° to 103.2°; pulse 80′, respirations 40′.

Without going too much into details, it is sufficient to state that the patient had eight chills in the six succeeding days. The highest temperature was 103.8°, pulse 80′, respiration 40′. The tenth day we were certain of marked changes in the heart sounds. These had come on so gradually that it was difficult to detect them. The systolic murmur at the apex was rougher and much louder, especially toward the axilla. The sounds were muffled over the base. Three days later we could detect a soft diastolic murmur over the base. The pulse was still regular but with a bounding quality and more easily compressed.

The night of the tenth day she was delirious. Some of the time she perspired very freely.

That day we ventured the diagnosis of malignant endocarditis. Previously we had been expecting pneumonia to develop. But the symptoms of the latter if they existed were very indistinct and soon cleared up.

The eleventh day of her illness there was a purulent discharge from her left ear. This ceased in two days, when the drum was incised without further discharge. At this time she complained of feeling dizzy, but never of pain.

The fourteenth day she was delirious and gradually became unconscious. Urine was passed involuntarily.

During the afternoon of the fourteenth day Drs. Gage and Baker saw the patient in consultation. At the time of the consultation Mrs. W. was unconscious, breathing regularly, pulse regular but bounding. There was no dyspnea, no edema of the legs, or signs of edema of the lungs. The heart sounds were as described above.

After considering all the possible causes for the patient's condition, Drs. Baker and Gage expressed it as their opinion that she was suffering from some septic condition in the brain, probably abscess, possibly meningitis.

Between 6 and 8 o'clock, P.M., of that day her respirations were of the Cheyne Stokes type with some cyanosis. The house officer, Dr. von Sholly, discovered a left-sided hemiplegia affecting the limbs and face but not the eye.

The next day the right side became paralyzed. She died the seventeenth day after the initial chill.

Résumé. — We have a woman past sixty; her family history negative. She has a rheumatic history and an old valvular heart lesion. There are recent evidences of either circulatory or brain disturbance, perhaps both. The onset of her last illness was marked by a chill and gastric disturbance, with a slight dullness and diminished respiratory sounds on one side. These symptoms were followed by a variable temperature for a few days, then by chills every day until unconsciousness came.

There was a marked leucocytosis; moderate renal changes; no diminution in the excretion of urea. There was increasing loss of mental power up to unconsciousness and paralysis. There was marked roughening of the heart sounds after a week's illness. The pulse was full and regular. There was no edema of the extremities or lungs, or other signs of cardiac incompetence.

DR. BAKER'S REPORT OF THE AUTOPSY.

Autopsy held at 4.30 o'clock, Feb. 22, 1903, — two hours after death. The body was that of a large, well-developed, well-nourished woman, 5 feet 11 inches in height; estimated weight, 185 pounds.

There was the usual postmortem mottling in dependent parts, but no rigor mortis. The pupils were equal and dilated about 7 mm. There was no edema. About each phalangeal joint there was marked bony and cartilaginous thickening, with some distortion of the fingers, evidently due to chronic rheumatoid arthritis.

Head. — The scalp showed nothing unusual, but the entire bony skull was found to be at least twice the average thickness, with marked thickening externally of the squamous portions of both temporal bones.

Interior of skull. — There were very extensive exostoses almost like ivory in character. They were situated nearly symmetrically, arising from the

petrous portion of the temporal bone extending into the middle fossæ.

Brain. — There was found a most extensive, yellowish-gray thick exudate in the pia mater, so extensive as to conceal the convolutions of the brain over nearly the entire surface of the convexity of the right hemisphere, and the upper two thirds of the convexity of the left hemisphere. The pia over the base was markedly injected and edematous, and somewhat hazy.

The main arterial trunks showed a moderate degree of atheroma.

The ventricles of the brain were not remarkable. On sectioning the brain no areas of softening were found.

Lungs. — The right lung was completely covered with old adhesions, completely obliterating the pleural cavity. There was also a very slight recent pleurisy about this lung. The lung itself was less elastic than normal, but there were no areas of consolidation. The left lung was fully expanded without adhesions. There were no areas of consolidation in this lung. The pleural cavity contained no excess of fluid.

Pericardium. — The pericardium was free from adhesions, except to the right lung. The sac contained about 30 cc. of a clear serous fluid.

Heart. — The heart weighed 400 gms. There was marked hypertrophy and dilatation of the left auricle, with marked hypertrophy of the wall of the left ventricle, which was nearly twice the normal thickness. The right auricle was not remarkable. The right ventricle was slightly hypertrophied but not dilated. The mitral orifice was somewhat contracted, with the anterior segment of the valve thickened. There was in it a small abscess containing about five drops of a thick yellowish-white pus. Adjacent to this was a large, irregularly shaped dark red thrombus, about the size of the end of a thumb. This was firmly adherent to the valve and projected into the auricle. The aortic valve was of normal appearance; but there was a slight degree of atheroma of the aorta itself just above the valve. The tricuspid and aortic valves showed no changes. The heart muscle showed a very faint degree of cloudy swelling.

Abdomen. — The stomach and intestines were normal. The spleen was about twice the normal size, with its lower half the seat of a recent hemorrhagic infarct. The remaining portion was soft and swollen. The left kidney was lobulate, firm and at least twice the normal size. Its capsule was thickened and adherent, leaving on removal a red granular surface. There were several small cysts scattered over the surface. On section the cortex was irregular in thickness, though measuring more than normal. The right kidney was lobulated, firm and of about one half the normal size. It was similar in structure to the left. The pelvis of the kidneys, ureters and bladder showed no special changes.

The liver was somewhat more fibrous than normal, without other changes.

The uterus was of the infantile type, about two inches in length, nearly round and about three quarters of an inch in diameter. (She had never menstruated.) Both ovaries were exceedingly small and apparently undeveloped, as were the Fallopian tubes.

ANATOMICAL DIAGNOSIS.

Malignant endocarditis of the mitral valve. Mitral stenosis and regurgitation. Hypertrophy of the left and right ventricles and hypertrophy and dilatation of the left auricle. Acute suppurative leptomeningitis.

Chronic interstitial nephritis, chronic fibrous pleuritis, acute splenic tumor with infarct. Infantile uterus. Thickening of skull. Rheumatoid arthritis of hands.

BACTERIOLOGICAL DIAGNOSIS.

Smear preparations from the brain showed numerous pneumococci, and a pure culture of pneumococcus was obtained from a culture on blood serum. Smears from the abscess in the mitral valve showed the same organisms. Sections of a portion of the mitral valve showed pneumococci.

I shall not attempt to discuss this case in detail, but speak only of a few of its most interesting features. Perhaps the first question that comes to mind is the source of the infection. There were no signs of recent pneumonia found at the autopsy, and we know that, aside from the doubtful respiratory symptoms, there were no other clinical symptoms of pneumonia. The middle ear as a source of infection was ruled out by the autopsy. The frontal or ethmoidal sinuses were not opened, so it cannot be definitely said that they were not diseased. Judging by the great thickening of the skull, it seems quite probable that one or both of them may have been completely filled up.

Cases of endocarditis with pneumococcus infection but without pneumonia, with and without meningitis, have been reported.

In an etiological table of meningitis Osler gives as a cause of primary meningitis, pneumococci — the meninges alone involved or in a general pneumococcic infection — or secondary meningitis due to pneumonia, endocarditis, etc., from pneumococcus infection.

Weichselbaum,[1] in 1888, reported two cases of malignant endocarditis without pneumonia either preceding or accompanying them; one with and the other without meningitis.

The one complicated by meningitis so nearly resembled my case that I consider it worth quoting:

"There was admitted to the hospital a man of thirty-seven years, who two years before had articular rheumatism, since which time he had suffered from heart palpitation. At the apex of the heart systolic and diastolic murmurs were found. During his illness the patient ran a high temperature, and had, besides, two chills. Twelve days after entrance to the hospital the man died.

"The autopsy showed a fibrino-purulent cerebrospinal meningitis; also an insufficiency of the mitral valve with considerable polypoid vegetations on the valve, an eccentric hypertrophy of the left and dilatation of the right heart ventricles. There was an infarct of the spleen. *Pneumonia* was not present. Pneumococci in the exudate of the meninges, as well as in the valve deposit."

[1] Wien. med. Wchnschr., 1888, Bd. xxxviii, S. 1177 and 1209.

In order to complete his investigations into the part the pneumococci played in this case, Weichselbaum, using a pure culture of these pneumococci, injected them into a guinea pig whose aortic valve had been injured artificially. After two days the pig died. The autopsy in this case showed an endocarditis, but not on the aortic valve which had been injured, but on the mitral valve. In addition there was a bilateral pleuro-pneumonia and a greatly swollen spleen. From the heart, spleen and lungs of the pig, cultures showed pneumococci.

Weichselbaum, in discussing these cases, says: "It must be determined which process was primary, the endocarditis or the meningitis. Since such a differentiation cannot be made with certainty, so nothing definite can be said about the point of entrance of the diplococcus pneumoniæ in the case described. This applies as well to the other case in which, besides the endocarditis, there was no process whatever to be found caused by the diplococcus pneumoniæ. The possibility of the endocarditis in this case arising by way of the respiratory tract cannot be shown offhand."

These last remarks apply to my case. It cannot be shown how the infection entered, nor exactly its course after entry. I have assumed that it extended from the heart to the brain. It may be objected to my opinion that Mrs. W. showed symptoms of cerebral disease of some sort before the onset of the acute illness. In reply I can only say that we do not know how long the malignant endocarditis may have existed prior to our discovery of it. Gibson[2] says: "This septicemic form of acute endocarditis is sometimes specially characterized by the cerebral symptoms to which Osler has particularly called attention; it is then frequently associated with meningitis, and it may be noted that Netter has detected pneumococci in the meningeal exudation. It cannot be too strongly insisted upon that a great many cases of the affection run a perfectly latent course, and only reveal themselves by a sudden disturbance of the circulatory system, through changes taking place in the heart or embolic processes occurring in other organs."

If for no other reason, this case is interesting because symptoms which were, at the best, but vaguely and partially understood were wholly explained by the pathological and bacteriological findings.

I am under obligations to Dr. F. H. Baker for a careful autopsy report; to Dr. Anna von Sholly for assistance and suggestions in the conduct of the case; to Dr. Merrick Lincoln for German translations.

Medical Progress.

REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BROOKLINE, MASS.

THE SIMPLE DEMENTED FORM OF DEMENTIA PRECOX.

DIEM[1], after a careful study of nineteen cases, concludes that, beside the clinical types of hebephrenia, katatonia, dementia paranoides and paranoid forms, which all end in the peculiar mental weakness of dementia precox, there is another type which leads to the same terminal condition, the same disturbance of intelligence and character, but its beginning is regularly simple, insidious and without special forebodings; it develops without acute exacerbations or remissions, without pronounced maniacal or melancholy states, without hallucinations and delusions, and without the peculiarities characteristic of the other forms of dementia precox above mentioned, catalepsy, tics, affectations, peculiar manners, stereotyped attitudes, negativeism and mutism. After some years there is usually a stationary condition. The type is best described by the name of the simple demented form of dementia precox or simple dementia. Pure cases are not very common, although they are much commoner than is supposed, because they often come very late to asylums. Twelve of the nineteen cases lacked all the specific symptoms of hebephrenia. A sharp definition, however, cannot be made and must be only artificial. Variations in the emotional state, katatonic symptoms, and delusions may at first be unnoticed, and yet be transitions to the forms already described. Women suffering from this form are often considered of bad character, and men simply as alcoholic. One symptom of dementia precox has seldom been described, but is specially common in these cases, namely, a fine regular tremor of the hands. It is usually impossible in the early stages to predict the definite course of the disease, and after a number of years the simple demented form may pass into the hebephrenic form. Simple dementia, hebephrenia katatonia and the paranoid forms of dementia precox thus form one clinical unity. This form is of great practical and forensic importance on account of its close relations to alcoholism, vagabondism and acquired anomalies of character.

PSEUDO-HALLUCINATIONS.

Lugaro[2] believes that there are many insane patients who apparently have hallucinations, yet merely have subjective impressions as of words pronounced mentally, and not actually false hearing. These pseudo-hallucinations or psychical hallucinations consist in pure representations without the objective character of true hallucinations. They consist in mental voices or the mental representations of acts. They assume a character extraneous to the person's personality by the method by which they arise, by their separation from the ordinary processes of association, by their unusual and strange character, and by the contrast which they may present to the patient's own desires. They are always interpreted by the patient as an exceptional phenomenon with explanatory delusions, which vary according to the patient's education or tendencies. The phenomenon of epigastric voices is determined by these hallucinations accompanied by abnormal sensations in the internal organs, which determine the localization of the voices. Many of the cases described as pure verbal psychomotor hallucinations are really due to these pseudo-hallucinations associated with peculiar sensations

[2] Diseases of Heart and Aorta, page 416.

[1] Archiv f. Psychiatrie, XXXVII, III, 1903.

[2] Rivista de Patologia Nerv. & Ment., VIII, 1, 72, Jan., Feb., 1903.

in the speech apparatus. The phenomena of thinking aloud and of forced speech may also be due to these pseudo-hallucinations. Certain imperative actions are also usually associated with them, and they all probably depend upon the same causal factor, — an irritation in the brain acting independently of the ordinary mechanism of association. True hallucinations probably have their seat in the sensory centers, and pseudo-hallucinations in the centers of association. They are characteristic of chronic mental states, or at least are more striking in them, and are especially common in dementia paranoides, but they may be observed in every form of dementia precox. They are also seen less frequently in psychoses of the climacteric period, or of old age, and sometimes in general paralysis. The characteristic mental disturbance of dementia precox consists in a disturbance of elaboration of motives for actions of the will and of conduct. All the affective disorders and the disturbance of conduct of such patients are due to this disturbance — the affective insensibility, the motiveless emotions, the impulses, the negativism, katatonia, catalepsy, echoing of words and acts, stereotyped movements and peculiar mannerisms. The pseudo-hallucinations are probably an immediate associative effect of such a disturbance. It is probable that this fundamental disturbance depends upon an elective systemic lesion of special cortical neurones. The system involved cannot be either sensory or motor, because the sensibility and the motor power are intact. It cannot be a system designed for the association of images, because memory and ideation are preserved. It must therefore involve a system of neurones destined for the highest co-ordination between representatives, the corresponding emotions and the execution of acts. From his studies of the structure of the cortex and the findings in patients presenting these phenomena, Lugaro suspects that the diseased system may be contained in the deep layer of the cortex and in the polymorphous cells.

DEMENTIA.

Probst[3] reports a case of dementia due to special changes in the cortex. The patient came of a healthy family, and had had no previous diseases or injury, although for six years she had taken considerable alcohol. At the age of twenty-one she began to be negligent and forgetful, confused and despondent. After three years she became restless, excited, irritable and at times violent, and slept poorly. This condition increased for two years, the patient becoming much demented, filthy and maniacal, caring nothing for her family or friends. This condition lasted to the end of her life, a period of eleven years. Four years before her death she had epileptic seizures, and later there was considerable hesitancy of speech and tremor of the hands. At the autopsy the left hemisphere was found much larger, extending beyond the median line, and the convolutions on the right side were small and atrophied. This atrophy was very great and sharply defined. It involved the right upper frontal convolution, the upper part of both right central convolutions, the extremity of the right temporal lobe, the orbital part of the first frontal convolution, the whole temporal lobe with the operculum and insula, the right supra-marginal convolution, the right gyrus fornicatus, the left upper frontal convolution, the orbital part of the first left frontal convolution, the left operculum and insula, and the left first temporal convolution. The atrophy of the cortex was, therefore, circumscribed and limited to the convolutions mentioned. The other convolutions were normal. The white matter beneath the convolutions was also much atrophied in places and showed secondary degeneration. There were no signs of inflammation or of obstruction of the circulation, but the process was apparently a primary destruction of the layer of the ganglion cells and later of the white substance. The disease came on slowly, and was first manifest in a brief period of confusion followed by three years of depression, negativism, and defective intelligence. This was followed by a maniacal stage, which lasted until the end. The hearing was not materially affected, but speech was limited to brief remarks, which were often repeated.

[3] Archiv. f. Psychiatrie, xxxvi, F. 62, 1903.

POLYNEURITIC PSYCHOSIS.

Meyer and Raecke[4] question whether this special psychosis described by Korsakow is limited to one definite cause, or whether it may occur under different conditions. Of late years it has been described as following infectious diseases of various sorts and also injuries, brain tumors, as one form of senile insanity, and from various poisons, although by far the commonest and most important cause is chronic alcoholism. The characteristics are the loss of the power of attention, disorientation, disturbances of memory and quiet confabulation. Hallucinations are not especially common. In the cases which they report there was often no neuritis. The first case had had delirium tremens, but showed no sign of neuritis or chronic alcoholism. There was great defect in appreciation of time and place; the memory for the past was good, but for later years, bad. The attention was much disturbed, and he had hallucinations of memory and confabulation. The second case was also alcoholic, and had had delirium tremens, but no neuritis. He had no memory for recent events, a tendency to romance, increasing mental weakness, and was untidy. The third case was also alcoholic, had no symptoms of neuritis, was dioriented, had hallucinations of memory, confabulation, disturbance of attention. The fourth case had a questionable neuritis, was much confused, had great failure of memory, especially for recent events. He was also anxious, and had grand ideas, delusions of persecution, and was somewhat depressed. The fifth case had had delirium tremens, disturbances in the pupils, disorientation, great loss of memory, and a tendency to romance. He had no epileptic attacks; there was cloudiness and thickening of the pia and atrophy of the convolutions with changes characteristic of general paralysis. The sixth case had had attacks of dizziness and convulsions in child-bed, with a complete loss of orientation for place and time and of memory for recent events. Alcohol was denied. The autopsy showed nothing remarkable, but suggested the early stages of general paralysis. In two other cases similar symptoms developed with apoplexy and a tumor of

[4] Archiv f. Psychiatrie, xxxvii, 1, 1903.

the brain. They believe, therefore, that the condition may appear in almost all the deep-seated organic lesions of the central nervous system, and almost always points to an irreparable injury. Other cases show that is not a disease of itself, and above all that it is by no means due exclusively to alcohol, but it may occur in general paralysis and in those diseases which cause severe and irreparable changes in the central nervous system.

PERIODIC INSANITY.

Neisser[5] calls attention to the fact that organic disease of the brain may give rise to periodical insanity, and cites the case of a woman of fifty-one who had an apoplectic attack with disturbance of speech and hemiplegia. The hemiplegia partly recovered, but within a year and a half she became very much depressed, and was sent to an asylum. Later she became tranquil, then much excited. In the interval certain residual delusions were detected dependent upon uncorrected impressions and defective recollections of the excited period. These periods of depression and excitement recurred, the periods of excitement being ushered in by spontaneous movements in the affected arm. He also calls attention to the fact that periodical insanity may not infrequently develop in patients who have had an attack of hemiplegia in childhood. In other cases where the prognosis is more favorable, a periodic insanity may develop after injury. He calls attention, furthermore, to one symptom of considerable importance, namely, that the pupils in patients between the attacks are abnormally dilated.

ACUTE CONFUSIONAL INSANITY.

Camia[6] has made a study of the pathological changes in fourteen cases of acute confusional insanity. He has also reviewed seven other cases which he has previously reported, and has reviewed the findings in fifty-three reported cases. He concludes that all the lesions met with in acute confusional insanity, except those due to complications or to changes which may be interpreted as etiological factors, are of an acute type, and due to a state of intoxication. Some present slight alterations of the chromatic substance of the cells in different parts of the nervous system, slight fatty degeneration of the cells of the liver and kidneys and sometimes a slight increase of nuclei in the walls of the vessels. These must be regarded as the minimal lesions attributable to the morbid process causing a mental disease, and common to all. Delirium tremens does not differ in any essential or characteristic trait from the ordinary syndrome of grave mental confusion, but the hallucinations of sight and the motor phenomena, especially the tremor, are more constant and more severe. We are not yet able to recognize the origin of the toxic substances which give rise to these conditions, and we are not justified in assuming a diminished resistance of the nervous system in such individuals, as the hereditary influence is often slight. There must, further, be some other factor still unknown, in regard to which we cannot yet make any hypothesis. In alcoholism we may suppose that the intoxication causes special alterations or organic change, which undergo great variations in different individuals, and thus be of a different nature in different individuals and produce different results. The same holds true in regard to the psychoses developing during convalescence from infectious diseases, and for the true febrile delirium. We must admit the existence of some intermediate factor to explain why certain cases run their course without any mental symptoms, and other cases develop severe mental symptoms in individuals who show no special indication of a diminished resistance of the nervous system. This factor may consist of a special virulence of the micro-organism, or changes in the organic chemistry from unknown causes. Other cases develop without any evident cause. In these we may argue whether some slight cause still obscure may produce the grave disturbance of the complex processes of the organic chemical changes. Camia recalls the opinion of Phillippen, that shock is nothing but an intoxication due to chemical alterations produced by the nervous system. The pathological anatomy does not explain the pathogenesis of many cases of acute confusional insanity. Among the factors which favor the development of such insanity, there is one which is adapted to the greater number and perhaps to all the cases even of a different origin. This factor consists in a special alteration of the chemical processes which may depend upon causes of a varied nature.

EPILEPTIC MANIA.

Heilbronner[7] believes that the flight of ideas is occasionally met with in acute epileptic psychoses, contrary to the opinion advanced by Kraeplin and his school; and cites a case with repeated attacks, the first being anxious excitement with great confusion and jactitation; in the second attack there was euphoria, the flight of ideas; the third attack was the same, except there was no disorientation, and the speech was in the main mere repetition. In some of the attacks the memory was retained, in others it was absent. In some of the attacks, furthermore, a depressed period followed the excitement. So he questions whether there may not be a combination of epilepsy with some other functional psychosis, and he believes that conditions may occur as an epileptic psychosis which cannot at first be distinguished from mania, and which especially may show very markedly the symptoms of the flight of ideas. He criticises the theories advanced by Kraeplin, and does not believe that any individual symptom may be regarded as typical or confirmatory of any definite idea that the flight of ideas may be pathognomonic of any special acute condition, but that it may be a symptom of various forms of mental disease.

THE MENTAL CONDITION IN APHASIA.

The question to be determined is how far organic aphasia, on account of the alteration of internal speech, determines mental enfeeblement, tending more or less to dementia. Vigoureux[8] reviews the various opinions that have been held; for example, that of Trousseau, who thought that in aphasics there was intellectual impairment; that of Charcot and Ballet, who considered that this impairment varied with the type of mind affected, that is, according

[5] Archiv f. Psychiatrie, xxxvi, 144, 1902.
[6] Rivista di Patologia nerv. e ment., vii, 289, July, 1902.
[7] Monatsschr. f. Psychiatrie, xiii, 193, 269, March, April, 1903.
[8] Vigoureux: Rev. de Psychiat., Jan., 1902.

as the individual condition is visual, auditory, etc. The appreciation of the intellectual ability is often a difficulty. There are a number of observations, for instance, in which sensorial aphasia with paraphasia may simulate dementia. Charpentier believes that among old chronic patients in asylums with apparent incoherence are a certain number of cases of paraphasia not understanding what they say, but well knowing what they wish to say.

The general conclusion of the author, after a study of the question, is that, while it is clear that a certain number of aphasic patients have been in full possession of their intellectual faculties in spite of their disorders of speech, yet the majority show intellectual enfeeblement and easily become demented.

POLYCLONUS IN GENERAL PARALYSIS.

Lambranzi[9] reports a case of typical general paralysis in a man of fifty-one, which began two years before his admission to the asylum with muscular spasms in the muscles of the lower limbs, especially of the thighs, and most marked in the flexor muscles. These twitchings came on at short intervals, and were sometimes so severe as to flex the thighs on the body and the legs on the thighs. Not long after, some weakness of the mental faculties was noticed; but he was able to continue in business for nearly a year, when other signs of general paralysis appeared. The muscular spasms were thus the first, and for a long time the sole, indication of severe brain disease.

ACUTE GENERAL PARALYSIS.

Buchholz[10] regards as acute general paralysis only those cases in which a previous healthy person was suddenly attacked with an acute form of the disease, and excludes the cases of acute manifestations in a person in whom the disease had begun in the ordinary manner. Out of 326 men paretics admitted to the Marburg asylum in twenty-five years, only 24 died within the first year, and of these 9 died of some intercurrent disease. Of the 15 remaining cases, in 9 the disease ran its course rapidly, but differed from the ordinary cases only in the brevity. In 2 other cases the disease ran its ordinary course, and then suddenly ended in a stage of great excitement. In the remaining 4 the symptoms resembled those of acute delirium, though some symptoms and the pathological appearances showed the true nature of the disease. Out of 50 women admitted during the same period 6 died in the first year, but only 1 from the disease itself. There are thus only 5 cases of the true acute galloping type. Clinically he distinguishes two forms,—the acute general paralysis, in which 11 of these cases might be classed, where the course is much shorter and rather more violent than ordinary general paralysis; and the galloping type, in which the short prodromal stage is followed by symptoms resembling those of acute delirium. The autopsies in these galloping types showed decided congestion of the cerebral vessels and also sub-acute and acute processes in the spinal cord. In one case it was believed that the chronic disease had received impetus and had been rendered acute by a course of mercurial inunction.

[10] Archiv f. Psychiatie, xxxvi, 427, 1902.

THE SENSE OF SMELL IN GENERAL PARALYSIS.

It has long been known that there is a tendency to loss of the sense of smell in general paralytics. A. Voisin, indeed, regarded this as one of the earliest signs, and therefore of diagnostic value.

Toulouse and Vaschide[11] find that complete loss of smell does not tend to appear at a very early stage (contrary to Voisin's opinion), and that it increases progressively with the course of the disease. Of the twenty-eight subjects, eight, or about one third, were absolutely anosmic, or quite without sense of smell, while among normal subjects only one in thirteen is found to be in this condition. None of the anosmic individuals belonged to those in the early stage of the disease.

It was noted that perception is lost much sooner than sensation, that is to say, that while the subject was vaguely conscious of some olfactory sensation when the camphor was applied, and could distinguish it from water, she was often unable to recognize the nature of the odor, even at an early stage of the disease. It is interesting to remark, the authors observe, that in a disease which is the very type of dementia, of intellectual weakness, the most delicate form of mental activity, perception, should be the first to go.

THE PATHOLOGY OF GENERAL PARALYSIS.

Fürstner[12] agrees in the main with Mendel that the classical form of the disease is becoming less common and that the type characterized by a simple progressive dementia is becoming more common. The disease is probably on the increase, although the statistics of asylums are not wholly trustworthy. He questions furthermore whether there is actually an increase of the disease in childhood. The duration of the disease seems to be shorter, about one half of his cases dying in the course of the second year. In 97 autopsies he found great atrophy only 9 times, hematoma only 6 times, and hydrocephalus 20 times. These gross changes seem much less frequent at the present time than in the autopsies formerly reported. This difference may be due to the prevalence of the demented form of the disease, and he recommends that especial attention be made to the postmortem findings in cases which have been carefully studied clinically. He believes that lesions found to-day are not sufficient to explain the more pronounced symptoms of the classical form of the disease. If the cases with a short initial period of excitement followed by a simple progressive dementia are regarded as belonging to the demented form, this form is much more common. He thinks that the term "tabo" paralysis should be limited to the cases presenting the typical symptoms of tabes, and these cases are decidedly in the minority. Pathologically he has found changes limited to the posterior columns in only 12% of the cases. In the majority of cases changes are found in both the lateral and posterior columns. He recommends that the term "pseudo-paralysis" be limited to the cases which at first show the symptoms of general paralysis, and later get

[11] Review de Psych., Feb., 1902.
[12] Monatsschr. f. Psychiatie, xii, 409, Nov., 1902.

well. He cites eight cases which showed an hereditary predisposition combined with mental and physical overwork and sexual excess, and which began with a period of excitement with exalted ideas, tremor of the facial muscles, unequal pupils, exaggerated knee jerks and some aphasia. All have recovered and have remained well for a number of years — from seven to eleven. Such cases can be explained only on the ground that the morbid changes in the brain cells disappear, and the cells recover their normal function.

THE BLOOD OF THE INSANE.

Ceni and Pini [13] have made another attempt to determine whether the blood of the insane has any special toxic power. From 200 to 250 cc. of blood was taken from the patient's arm, and allowed to coagulate for twenty-four hours. The serum was then collected and injected into the peritoneal cavity of guinea pigs. The blood from two normal individuals and eighty-one insane persons was employed. In the first series of tests, three tests were made injecting 2½, 5 and 10 cc. respectively. In the second series the dose was increased, injecting 5, 10 and 20 cc. As a result of these injections they conclude that it is impossible, notwithstanding the large number of experiments, to establish by this method any definite differences of a general nature between the toxic power of the blood serum of normal individuals and that of the insane. The greatest number of cases with a hypertoxic serum were found in melancholia, epilepsy and phrenasthenia. The toxic power of the blood serum of individuals affected with different forms of insanity did not present any constant variations worthy of note, nor were these noted in different phases of quiet and excitement in one and the same morbid form. The phenomena of the individual reaction of the animals are so frequent as to disturb the accuracy of the results. By the method employed it was found impossible to control the phenomena of hypotoxicity of the serum found by other observers in melancholia, dementia and in epileptics between the attacks.

ASSISTANCE AND FAMILY CARE OF THE INSANE IN ITALY.

Tamburini [14] notes the increasing number of the insane in Italy, which has trebled in a little more than twenty years. This has naturally led to a great overcrowding of all the asylums in Italy. Of nearly 37,000 insane now registered in Italy, he believes that nearly a third — about 10,000 — could be cared for in some other way than by treatment in an asylum. This great increase in the number of the insane has necessarily led to a very much greater increase in the cost of providing for them, the cost in the provinces of Rome and Florence amounting to a million liras annually. As a relief for this it has been proposed to limit the admission of certain classes of insane, to establish special institutions for certain classes, such as epileptics, alcoholics and the pellagrous, and the development of family care. In 1898 about 1,400 insane were cared for in private families, either in their own families or in other families, in both cases with assistance from the state. The method of domestic custody in the patient's own family has many disadvantages. It may, however, be permitted in certain cases where the director of the asylum is convinced that the family environment is really proper for the good physical and moral treatment of the patients, and when the patients thus entrusted to the family remain under the careful watch of the asylum by means of one or more medical visitors, who may inspect them frequently, and may control the physical and moral treatment of the patient.

The care in the family of strangers was introduced in July, 1897, and at first was not wholly successful, because the patients were boarded out without any regulation or oversight. This is a method to be absolutely condemned. Under proper oversight, however, and with proper selection of patients, the method has great advantages. Quiet chronic insane of the asylum are often desirous to be boarded out, and some prefer it to being with their own families. The families in the neighborhood of the asylums have now lost the distrust and suspicion of this form of assistance and recognize the convenience of it. There are an increasing number of requests for patients, even from people who have had no relations with the asylums. The experience of the last few years has shown the necessity of a prudent choice of patients to be boarded out, drawing them especially from the quiet, harmless, chronic insane, not excluding the forms of periodic, epileptic or hysterical insanity and the harmless paranoiac insane, and in some cases convalescents. A careful choice of the families should be made, the families of asylum attendants to be preferred who live not far from the asylum, and who offer guarantees of morality and trustworthiness, which are indispensable. Careful observation on the part of the government of the asylum is requisite. The colony and family care have both their advantages and their inconveniences, but both have their place. In Italy the best method to adopt is to entrust the patients to families in towns near the asylum under the oversight of asylum physicians. This system offers the advantage of being under the initiative of the director of the asylum, and will lead the way to what Tamburini regards as the ideal, — the care of insane in small asylums for the treatment of acute and dangerous cases, and in large farm colonies with family life for all the rest.

ARTERIAL DISEASE IN INSANITY.

In an analysis by Greenlees of the pathological findings in 232 insane patients, thickening of the walls or calcareous deposits, as found (*a*) in the main arteries of the body, and (*b*) in the cerebral arteries, were frequently noted conditions. Hypertrophy of the arterial muscular coat, and atheromatous deposit in the vessel, are conditions common to old age, even in the sane; but it is interesting to note that in general paralysis, and this in cases dying at a comparatively early age, one or other of these conditions was commonly found affecting not only the general arterial system, but also the cerebral arteries. While arterial disease was found in 20% of cases of "mania," it occurred in 60% of my cases of general paralysis; in the former disease it was only found in cases of long-standing disease, whereas the average duration of the latter disease is only about three years.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

TWENTY-FOURTH ANNUAL MEETING, WASHINGTON, D.C.

(Concluded from No. 1, page 20.)

DR. GEORGE H. MONKS of Boston read a paper entitled

INTESTINAL LOCALIZATION; A STUDY ON THE CADAVER FOR THE PURPOSE OF DETERMINING TO WHAT EXTENT THE VARIOUS PARTS OF THE SMALL INTESTINE MAY BE IDENTIFIED THROUGH AN ABDOMINAL WOUND,

and reported a series of investigations on forty cadavers. The small intestine and mesentery in twenty-four of these cadavers were examined in reference to such characteristics of the different parts as might be of use in assisting the surgeon to determine the *position* of any loop of intestine in reference to the rest of the tube; and also to ascertain the *direction* of the tube in the loop (that is to say, which end of the loop was nearest the duodenum and which the ileo-cecal valve). Tests were made through various abdominal incisions on sixteen other cadavers to determine with how small an error a loop could actually be localized. Of the 180 loops localized, the average error proved to be about two feet.

The attempt to ascertain the direction of the gut was made in ninety different loops on fifteen different cadavers, and in eight the direction proved to be wrong, while in 82, or 91%, it was right.

An intestinal loop was localized principally from the characteristics of the loop itself, or from those of the adjacent mesentery, or from the relation of the loop to the deeper parts of the mesentery. The direction was ascertained by reference to the mesenteric route, which is an infallible guide, although, on account of the twists in the mesentery, it was occasionally difficult to properly apply the test.

A number of diagrams were exhibited illustrating the characteristics of the different parts of the intestinal tube and of the mesentery, and the writer stated that he had, on a number of occasions, determined the position and direction of an intestinal loop on the living subject by this method with success, due allowance being made for the different conditions.

This paper was discussed by DRS. W. W. KEEN of Philadelphia, and GEORGE WOOLSEY of New York, and closed by the author.

DR. LOUIS A. LAGARDE, Washington, D. C., read a paper entitled

THE LESIONS THAT AUGMENT THE DEVELOPMENT OF TETANUS AND OTHER INFECTIONS IN GUNSHOT WOUNDS,

in which he expressed the opinion that the lesions would depend upon: (1) The sectional area of the bullet; (2) its velocity, and (3) the resistance encountered on its impact. The greater the sectional area or velocity of the bullet, the greater will be the lesion. Hematomata especially predispose to infection and increase the danger from tetanus, as is also the case when the wound is burned by powder, etc. He reviewed the observations of Dr. Lardy in the Greco-Turkish War, and also contrasted the lesions made by the various kinds of bullets. He referred to the experiments of Muller and Koller, on which they essayed various methods of treatment of the channel track in gunshot wounds caused by projectiles that were primarily infected, namely: (1) Controls, for which nothing was done; (2) those treated with a glass drain; (3) those treated with iodoform gauze drain; (4) those irrigated with 5% solution of carbolic acid; (5) those treated by rubbing with a cotton mop soaked in tincture of iodine; (6) those treated by cauterizing the wound. All the wounds were dressed with a clean sterile dressing, and the results showed that the animals treated by simple dressing did best of all, and that those treated by radical measures, such as swabbing with iodine and the application of the thermocautery, gave evidence of suppuration in every instance.

THURSDAY AFTERNOON.

DR. EMMET RIXFORD, San Francisco, Cal., read a paper entitled

NOTE ON THE OPERATIVE TREATMENT OF OLD UNREDUCED DISLOCATIONS OF THE ELBOW,

in which he remarked that the keynote to the situation was sounded by Stenson in a paper read before this association in 1891, in which he showed that the so-called fragments of bone which had frequently been observed within the joint, while unquestionably the chief obstacle to the reduction of the dislocation, were in a great majority of cases not fragments broken off the humerus or ulna by complicating fracture, but new growths of bone from stripped-up periosteum. He felt that, if the bone be reduced to its normal position shortly after the injury, which is nearly always possible, the function is practically in every case restored; but if allowed to remain displaced until this new bone has formed, manipulative reduction is impossible and should never be attempted if force is required. The reason that congenital dislocations treated by manipulative force recovered, he felt, was due to the fact that this new growth of bone had not formed, and also that the operation being done in children the joint would often recover from the traumatism.

He then reported cases in which he had employed the Kocher incision, but because of the difficulty in reducing the dislocation, and fear of loosening the periosteum, he had added the procedure of Trendenberg of section of the olecranon. He commented on the value of the x-ray as a diagnostic aid.

This paper was discussed by DRS. JOHN B. MURPHY of Chicago and A. H. FERGUSON of Chicago, and closed by the author.

DR. E. WYLLYS ANDREWS, Chicago, Ill., read a paper entitled

DROWNING OF PATIENTS IN FECAL VOMIT DURING OPERATIONS FOR INTESTINAL OBSTRUCTION AND SEPTIC PERITONITIS,

in which, after reporting two cases which had occurred in his own practice and referring to several cases that had happened in the practice of others,

he summed up as follows: (1) Flooding of the air passages by fecal vomit is a real danger, and probably has caused many unexplained deaths. (2) Resuscitation is impossible or very difficult. (3) The fluid may flow by gravity through the relaxed stomach sphincters directly out of the intestines, where it has accumulated in enormous quantities. (4) The accident occurs with great suddenness with a stomach supposedly empty. The suffocation may be so complete that no outcry is made and may not be noticed by the attendant. (5) It may occur as late as an hour after anesthesia, or at any time until consciousness is restored. (6) We have no evidence that it can occur during consciousness, even *in extremis*. (7) After septic laparotomy, patients when returned to bed should be watched, without even momentary intervals, to full consciousness. (8) A suggestion made to me by Dr. McArthur that as many as possible of such cases be operated upon under cocaine anesthesia seems to me sound in the light of the above report, as well as for other reasons. I have tried both spinal and local cocaine anesthesia in several recent cases, and am convinced that it is a life-saving measure.

This paper was discussed by DR. J. M. T. FINNEY of Baltimore.

THE PATHOLOGY AND TREATMENT OF TARDY POST-OPERATIVE INTESTINAL OBSTRUCTION, WITH A REPORT OF CASES

was the title of a paper read by DR. ELLSWORTH ELIOT, New York, in which he called attention to the fact that it is not a rare occurrence, being most frequently caused by paralysis of peristaltic action from a spreading or septic peritonitis; it occurs less frequently after a laparotomy from a nonpurulent condition, even although no infectious material has been introduced at the time of the operation. In this latter group of cases the obstruction is usually of a mechanical nature, and is due to the angular adhesion of one or more loops of intestine to the parietal peritoneum, to each other, or to the stump of some recently resected pedicle of omentum or ligated base of tumor, to a possible valvulus or to the protrusion of a coil of intestine through some accidental orifice in the mesentery or some other peritoneal structure. The symptoms indicating the obstruction develop shortly after the operation and before restoration of the intestinal function has taken place.

Careful exclusion of any kind of mechanical, thermal or chemical irritants from the contents of the abdomen during the primary observation should be observed. Ligatures should not be needlessly employed, drainage should be carefully managed and changed early with subsequent diminution in its amount, or if possible, its complete removal, while the actual treatment does not differ from the treatment of obstruction arising from any other cause. Several cases resulting from various causes, among them being two following operation for appendicitis, were reported.

This paper was discussed by DRS. JAMES E. MOORE of Minneapolis, J. F. BINNIE of Kansas City and A. J. OCHSNER of Chicago, and closed by the author.

DR. F. E. BUNTS, Cleveland, Ohio, read a paper entitled

NERVE INJURIES ABOUT THE SHOULDER JOINT,

in which he called attention to the distinguishing clinical nature of these injuries, which is a striking deformity resulting from the muscular atrophy, and the loss of function dependent upon the nerve injured and the muscle involved. He directed particular attention to: (1) Paralysis of the circumflex nerve; (2) paralysis of the long thoracic nerve, and (3) paralysis of the suprascapular nerve. He then gave in detail the symptoms produced by injuries to each of these nerves, giving a careful résumé of the literature on the subject, together with a tabulated report of cases showing the various diagnostic and prognostic points.

Under the head of general treatment and considerations, he stated that he had not referred to the individual treatment of these paralyses, as what applies to one is equally appropriate to all. The after-treatment in most cases has been the various anti-rheumatic preparations, and later electricity and massage. Where the cause is evidently a sudden traumatism, cold and rest are the most beneficial local measures during the acute stages.

He stated that he did not desire to advance any new or improved method of treatment, as the methods now in vogue have proven fairly satisfactory, so far as medical measures go, but that he had endeavored to point out in each case, as far as he was able, the synergistic action of other muscles which might, by careful and intelligent development, be so exaggerated or altered in their functions as to take the place of those which are totally or partially paralyzed.

DR. GEORGE WOOLSEY, New York, read a paper entitled

A CONTRIBUTION TO THE SURGERY OF CEREBRAL TUMORS,

in which he called attention to the fact that only a small proportion of all cerebral tumors were fit to be made the subject of radical operation, varying from 2 to 8%, according to various observers by the autopsy records, and averaging about 16%, judging from the records of those clinically diagnosed. He felt that this small percentage of operable cases depended largely upon our imperfect means of exact diagnosis and localization and on the inaccessibility of certain parts of the brain to surgical operation. In arriving at a diagnosis, we must consider, first, the general or pressure symptoms, and, second, the focal or localizing symptoms.

He then gave a careful résumé of the history of 101 cases reported by various authors during the past five years, and after going at some length into the diagnosis, prognosis and operative technique, concluded as follows: (1) The sphere of operation for cerebral tumors may be and has been extended to those parts of the cortex where the tumors are accessible and localizable, that is, to the prefrontal, parietal and occipital regions in addition to the motor area. (2) The prognosis, both immediate and remote, is as good, or even better, than in operations for malignant growths in some other locations. (3) This prognosis has improved with

the improvements in localization and operative technique, and with the limitations of radical operations to cases accurately localized. (4) The palliative operation is strongly indicated to relieve the symptoms where localization cannot be accurately made or the tumor cannot be removed. The exploratory operation is contraindicated. (5) Practically all circumscribed growths of moderate size are suitable for operation. (6) The osteoplastic method should be employed and the most rapid (and perfect) technique adopted which the circumstances allow.

This paper was discussed by DR. F. E. BUNTS of Cleveland, but not closed by the author.

DR. EDWARD MARTIN, Philadelphia, read a paper entitled

THE TREATMENT OF SURGICAL SHOCK BY ADRENALIN,

in which he referred to the experiments of Reichert, which have shown that adrenalin intravenously injected is a direct stimulant to the heart and to both the centric and peripheral vasomotor systems. He also notes that it is a stimulant to the respiratory center and that it increases general metabolism and body temperature. The brilliant experiments of Crile corroborate these findings, and would seem to point toward adrenalin as a potent medication in the treatment of shock or collapse. He also referred to the fact that in so far as the immediate lethal effects are concerned the drug is not markedly toxic, at least in the doses in which it would ordinarily be administered, since while .0005 dr. will markedly increase the blood pressure, this dose increased a hundredfold simply accentuates the increase, nor is there subsequently a compensating drop. He gave a full résumé of the experiments with this drug upon animals, and then followed a series of several clinical cases in which it had been used, one being a typhoid perforation and another a case of amputation at the hip joint required by osteomyelitis. He felt that the case of typhoid perforation spoke strongly in favor of the employment of this drug, as he stated he had never before seen a surgical patient so profoundly septic and collapsed make an operative recovery. He did not feel that the results of laboratory experiments should be taken as absolute indications of what the effect might be when employed on the human subject, and because of its power of lessening the bacteriolytic power of the blood of animals, he recommended that it be used in cases of infection in the human subject with caution until its exact effect has been demonstrated.

This paper was discussed by DR. EMMET RIXFORD of San Francisco.

DR. W. W. KEEN and DR. WM. M. SWEET reported the case of a boy of fifteen who on Oct. 24, 1902, was shot in the forehead. The bullet entered the right side of the forehead a half inch above the eyebrow and did not emerge. The wound was cleansed and a sliver of bullet removed from just above the wound of entrance. The left leg became entirely paralyzed, and on the day after the accident he had half a dozen severe epileptiform convulsions, but none since then. In the course of three months he was able to get about and when first seen by the authors, April 9, 1903, the only remnant of the injury was a slight weakness in the left leg.

Dr. Sweet made a skiagraph of the head and located the principal portion of the ball at a point 2.2 cm. to the right of the middle line and 1.5 cm. back of the fissure of Rolando and at a depth of 5 cm. from the top of the head. The position of the ball corresponded with Plate No. 15, of Dalton's Transverse Sections of the Brain, and measurements showed that the ball lay just above the right lateral ventricle. In addition to this large fragment, there were seven other minute fragments, the largest one being about the size of a medium-sized pin's head. These lay 2 to 3 cm. above a line running from the wound of entrance to the present position of the ball. The ball was not lying in the leg center.

The conclusion reached, therefore, both by reason of the finding of the fragment 2.5 cm. *above* the wound of entrance, the position of the smaller fragments *above* a direct line from the wound of entrance to the present position of the bullet, by the boy's statement that his head was only slightly bent at the time of the accident and by the injury of the leg center, that the ball went upward and backward, struck on the inside of the skull at a point corresponding to the leg center and was deflected downward and backward to its present location.

It was decided, therefore, that it would do more harm, at present, to attempt to remove the ball than to let it alone, but that if symptoms of an abscess or a single epileptic attack should follow, the ball should be removed at once.

Dr. Sweet described in detail his new modified apparatus for the exact location of such foreign bodies.

DR. W. JOSEPH HEARN of Philadelphia showed a skiagraph of a case in which operation was shown by Sweet's method to be advisable, and was performed successfully.

DR. EMMET RIXFORD of San Francisco discussed the paper, and DRS. W. J. MAYO of Rochester, Minn. and N. B. Carson of St. Louis briefly reported similar cases occurring in their own experience.

The following papers were read by title:

THE TOILETTE OF THE PERITONEUM AFTER OPERATIONS OF THE BILIARY PASSAGES. DR. EDWARD MARTIN, PHILADELPHIA.

AN UNUSUAL FORM OF SARCOMA OF THE TENDONS. DR. ROBERT F. WEIR, NEW YORK.

REMOVAL OF HEAVY SILK LIGATURE FROM AROUND THE PNEUMOGASTRIC NERVE. CLINICAL SYMPTOMS BEFORE AND AFTER REMOVAL. DR. CHARLES A. POWERS, DENVER.

The following officers are elected for the year 1903–1904: President, Dr. N. P. Dandridge, Cincinnati; Secretary, Dr. Dudley P. Allen, Cleveland; Treasurer, Dr. George R. Fowler, Brooklyn; Recorder, Dr. Richard N. Harte, Philadelphia.

The place of the next meeting, St. Louis, some time in May, 1904.

THE BOSTON
Medical and Surgical Journal

THURSDAY, JULY 9, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SCIENTIFIC WORK IN PSYCHIATRY.

THE spirit of research which during the last century has pervaded all fields of human activity, and which has never been more active than in recent years, has exerted a potent influence on the institutions for the care of the insane throughout the world. From Pinel's day what had been virtually *prisons* began to become asylums. Forty years ago they began to change, owing largely to Griesinger's activity, from *asylums* to *hospitals*. This latter change was slow at first, but has advanced more and more rapidly, especially in the last decade. It has involved different conceptions and methods from those formerly in vogue — the inmates are becoming "patients," not "boarders;" their care-takers are becoming "nurses," not "keepers," and are more and more being trained in their duties; the medical staffs are increasing relatively to the number of patients; the patients are being more carefully observed and studied as to their mental and physical conditions; active treatment is being better directed to the improvement of these conditions; careful search for and scientific investigation of the causes underlying these conditions are being instituted; and instruction to students is being given.

In all countries there are still some asylums. The majority of institutions in this country have, however, at least begun to be hospitalized, while some have caught the real spirit and full significance of the movement. Their annual reports generally show pretty clearly their stage of progress. Some, with large capacity, small medical staff, relatively few admissions and discharges in proportion to the capacity, are hardly out of the asylum stage — their reports deal only with financial and administrative matters. Others have increased the relative size of the medical staff, established clinical laboratories and infirmary wards, train their nurses, and seek to give special care to recent cases. Their reports give, in addition to the financial and administrative data, statistics as to the number of autopsies, blood counts, urine analyses, sputum examinations and Widal tests, and other bacteriological examinations. Such institutions are becoming hospitals; and the work they do, while not advancing the bounds of our knowledge of insanity, yet indicates the growth of the hospital idea and the part these institutions are taking in it, and marks distinct progress towards a higher goal. A few institutions are in reality hospitals in the fullest sense of the term — places not only for the care and treatment of patients, but for the study of their conditions, the investigation of the causes of the conditions, and the spread of knowledge thus gained through instruction to students. This is notably true of the McLean Hospital at Waverley in this state, the annual report of which has recently appeared. The record of the work which it has undertaken and is carrying on and the methods employed in pursuance of this work invite comparison with the best of similar institutions in this or other countries. According to this record, the year just passed marks progress especially in the line of chemical investigation into the metabolic changes which may reasonably be considered to underlie the phenomena of many mental diseases. This work is the logical and normal development of a line of research conceived in the early 80's, begun in a small way with inadequate laboratory facilities and untrained workers in the late 80's, advanced during the following decade in enlarged laboratories but still by assistants not specially trained in the methods of physiological chemistry, but now, and for the last three years, being prosecuted in a thoroughly well-equipped laboratory by physiological chemists whose published papers have received recognition in the special journals and laboratories both in this country and abroad.

"Chemical laboratories" are shown in the plans of the buildings built within the last ten years in Germany in connection with the psycho-physical and pathological laboratories in the psychiatrical clinics, as at Giessen, Würzburg, Kiel, etc., but it does not appear that more is being done in them than the routine investigations involved in the ordinary thorough medical examination of patients. The attitude of the directors of these clinics is well expressed by Gaupp as late as January of this year. While recognizing that chemistry "may give us a certain insight into the relations between bodily and mental processes sooner than anatomy," he says, nevertheless, that it "is as yet unable to give us even a foundation" on which to work; we

must wait until "science understands fully the albumen bodies" and "all vitalistic questions have been once and forever done away with;" "only then can we satisfactorily begin to study the chemical processes in the organism." In other words, they do not yet see problems at which they can work in the present stage of development of physiological chemistry. England has held a broader conception of the possibilities of chemical investigation; as shown by the papers of Haliburton and Mott of London, published in 1899 and subsequently, on choline in conditions of nerve degeneration, and by the taking up under Mott's guidance of problems of pathological chemistry in these recent years at the Pathological Institute of the London County Asylums at Claybury.

Not only in the line of chemical research, organized and pursued for so many years with distinct purpose, but also in other lines of investigation, such as the clinical observation of mental and bodily states, the McLean Hospital is not behind the best of European institutions. Its methods of history and case-taking are thorough and adequate, gathering full data for present and future study. Its psychological laboratory, established in 1890, with a trained assistant, antedated Kræpelin's at Heidelberg by a year, though for some years before that Kræpelin had been seeking to adapt the methods of physiological psychology to the study of psychiatry. Clinical papers of value have been published by members of the hospital staff in journals and books of reference. The pathological-anatomical laboratory has contributed, through members of the staff, to the literature of lesions of the nervous system. Studies on the effects of certain modes of hydrotherapeutic treatment have been made and some of the results reported to medical societies, though not yet published. In the matter of treatment, besides other methods, new as well as old, the "bed-treatment," which is now being extensively discussed and introduced in foreign hospitals, has here been used in certain cases for many years. Since 1882 the nursing force has been trained, and the assignment of women nurses to the care of male patients has been made a prominent feature of the training-school system for twenty years. This practice is but newly attracting attention abroad, although for several years in a few hospitals the services of women in male wards have been used to a very limited extent.

We may well have a feeling of justifiable pride in an institution that takes such a leading position among others of its class. Its work not only reflects credit upon the community, but is productive of inestimable benefit, not only to the patients who are cared for in it, but to those also of other hospitals. For there is not wanting evidence that others profit by its leadership. But such work as is there being carried on must receive generous support if it is to be maintained, and therefore it not only imposes a duty on the community that benefits by it, but creates a great opportunity as well. It opens the way for an entirely new line of philanthropy — the endowment of research work in hospitals for the insane. The character and quality of the work already done at the McLean Hospital is guarantee of what it would be under the more favorable conditions of permanent endowment; the standing of its managers is guarantee of the faithful administration of such a trust. It is worthy in all ways to be the recipient and trustee of an adequate endowment. May it not have long to wait for such an increment to its power for good!

BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.

THERE has recently been organized in this city an association for the relief and control of tuberculosis, with the general object of demonstrating the prevalence of tuberculosis in Boston, and showing how it may be eradicated by intelligent effort. More in detail the object of this society is to make a careful study in this city of the relations between tuberculosis and the general conditions of life, also to extend as widely as possible knowledge regarding the communicability of tuberculosis by means of pamphlets, circulars and lectures, and to arouse general interest in procuring proper hospital treatment both for early and late cases, and for the care of the very poor as well as of those able to pay moderate fees. Finally it is intended to co-operate with various hospitals and dispensaries, where tuberculosis is under treatment, with the District Nursing Association, the Associated Charities and other organizations in caring by every possible means for indigent consumptives.

In the circular sent out by the association, it is stated that the work will be not only for the improvement of the condition of consumptives in Boston, but also for the permanent improvement of conditions in the community. It is estimated that about 1,200 deaths from consumption are annually reported to the Boston Board of Health, and that there are in the city in the neighborhood of 3,600 persons in various stages of the disease. It has been shown conclusively that many of these incipient cases, if given proper treatment in time, might be cured, and with this fact goes the hope that tuberculosis may ultimately be entirely eradicated.

Associations similar to this have been formed in America and Europe, and are already showing good cause for the support which has been given them. Naturally such work can only be carried on under a very considerable expense, and it is estimated that $5,000 is at once needed. The work is in the hands of physicians and others identified in the community with progressive ideas and work in connection with the general subject of tuberculosis as well as with other worthy objects. Under this leadership the public may be sure that the work will be well and conscientiously done, and that any contributions offered will be wisely expended. In general, as we have frequently said in these columns, we are in entire accord with any movement which will spread in an intelligent manner the fundamental facts regarding tuberculosis. Commonplace as these facts have become to the more enlightened portion of the community, it is plainly evident that there is still and long will be opportunity for active missionary work among the poor, and it is in this class that the disease gets its firmest foothold and is most difficult to eradicate.

We are glad to note in the circular which has been sent out that the work of the association by no means consists alone in influencing legislation or public opinion in the matter of increased hospital facilities for consumptives. What we need more than this at the present time is a general recognition of the fact that until the centers of infection can be wholly eradicated hope for the disappearance of the disease must be deferred.

THE REGENERATION OF SPINAL NERVE ROOTS.

We have previously commented editorially on an operation for trifacial neuralgia, suggested by Drs. C. H. Frazier and William G. Spiller of Philadelphia, consisting in a section of the nerve between the Gasserian ganglion and its entrance into the pons. The advantage of this operation was held to be that it was far less violent than destruction of the ganglion itself, and less liable to dangerous hemorrhage, and relatively simple of accomplishment. Its virtue, however, depended wholly upon the fact that the nerve roots were presumed not to have the power of regeneration.

To further substantiate this latter point, Spiller and Frazier have recently published in the University of Pennsylvania *Medical Bulletin* the results of an experimental study on the "Regeneration of Posterior Spinal Roots." The relative ease of operating on spinal roots, and the probable identity of the reactions in this and cranial nerves, led them to employ the spinal roots for their investigation. The operations, which were performed on dogs, were carried out with most careful aseptic precautions, and also the roots were divided in such a way as to make most favorable provision for subsequent reunion, if such reunion could occur. The general result of this investigation, the details of which we need not enter upon, was that there was no evidence in the case most favorable for observation, in which the animal lived ten months, of regeneration of these cut nerves.

This result naturally justifies the claim previously made by these observers, that a similar operation undertaken on the fifth nerve for the relief of pain should be permanent. As opposed to this view, there is a certain amount of evidence which goes to show that regeneration may occur in the intramedullary portion of severed posterior nerve roots. The evidence, however, remains somewhat inconclusive, and further experimentation must, no doubt, be undertaken before anything absolutely definite may be claimed. The fact remains, however, that Spiller's experiment, so far as it goes, is of positive value, and should encourage surgeons to resort to the operation to which we have alluded on the fifth nerve, certainly in cases where the extirpation of the Gasserian ganglion is for any reason contraindicated.

MEDICAL NOTES.

Mortality in Chicago. — According to the bulletin of the Chicago Health Department, the remarkably low mortality rate of the month continued during the week ending June 27. The 454 deaths reported — only three more than the week before — represent an annual rate of 12.54 per 1,000 of the department's conservative estimate of Chicago's midyear population, 1,885,000. For the twenty-seven days of the month the rate has been 12.70, as compared with 13.12 for June, 1902, and with an average of 14.12 for the ten Junes of 1893–1902 inclusive.

Swiss Medical Congress. — The Congress of Swiss Physicians was held at Lausanne in the early part of June. Anti-diphtheria serum, goiter and chronic articular rheumatism were among the subjects discussed.

Dr. Howard A. Kelly Honored. — Dr. Howard A. Kelly has recently been elected honorary president of the Glasgow Obstetrical and Gynecological Society. The subject of his presidential address, given in Glasgow, June 17, was, "The History of Appendicitis in Great Britain." The *British Medical Journal* comments upon it in the following words: "The address was interesting

and racy, and was evidently meant as a compliment to British physicians and surgeons. Needless to say, it was enthusiastically received."

RETIREMENT OF SIR FREDERICK TREVES. — It is reported that Sir Frederick Treves is about to retire from the practice of medicine. In the report to which we have access no reason is given for this retirement beyond his inclination to devote himself to other matters than medicine during the remainder of his life.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 8, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 37, scarlatina 24, typhoid fever 20, measles 31, smallpox 0.

CONDEMNATION OF SIASCONSET WATER SUPPLY. — It is reported that the State Board of Health, having examined the water at present used in the village of Siasconset, Nantucket, has reported that it is too polluted for drinking purposes without preliminary boiling. Last year typhoid fever, presumably due to the water supply, appeared in the village, but nevertheless effort to secure a public water supply has hitherto been unavailing.

SCARLET FEVER. — There has been a considerable epidemic of scarlet fever in Woburn, so that for a time the Board of Health saw fit to recommend suspension of public gatherings. Schools have been closed, and the question of closing churches was agitated. The type of disease has been mild.

THE BOSTON FLOATING HOSPITAL. — The Board of Managers of the Floating Hospital have announced the opening of the season of 1903 on Tuesday, July 7. Trips down the harbor will be made daily (weather permitting), except on Sundays, from July 7 to a date in September to be determined later. On Sundays, every night, and up to eight o'clock in the morning, patients will be admitted to the hospital at the station, Pickert's Wharf, New Street, East Boston, near North Ferry. The daily trips will be made from City Wharf, South Ferry, Eastern Avenue, the hospital leaving at 9.30 A.M., and returning about 4 P.M. Patients will be received at these hours. The age limit for patients is six years. The requirement for admission is a certificate signed by a physician, and these may be obtained from the Floating Hospital Office, 178 Devonshire Street, Room 505, from any of the dispensaries and hospitals in the city, and from physicians and agents of charity organizations in the city proper as well as in Greater Boston. Admission cards will be sent by mail on application. Co-operation is earnestly requested in the effort to exclude all contagious diseases from the hospital.

NEW YORK.

SUMMER CORPS OF BOARD OF HEALTH. — The summer corps of the Board of Health, organized for service in the tenement districts during the present season, commenced its work on June 29. This is somewhat earlier than usual, which is a distinct advantage, and will, no doubt, result in a greater saving of infant life. This year the corps consists of forty-three medical inspectors and seventeen trained nurses, a considerably larger number of nurses than last season. There are already entered at the health department the names of about twenty thousand infants and young children, and it is expected that before the summer is over there will be at least double this number.

JUNE MORTALITY. — The lowest mortality for the present year, and possibly for a number of years past, was recorded during the month of June. The health department reports show that this represented an annual death-rate of 16.54, against 18.51 for the month of May and 17.99 for June, 1902. Among the diseases presenting a decline in mortality were the following: The weekly average of deaths from pneumonia decreased from 149¾ in May to 84½ in June; the weekly average of deaths from broncho-pneumonia, from 62½ to 52¼; from acute bronchitis, from 36½ to 20½; from pulmonary tuberculosis, from 154½ to 139¼; from Bright's disease and nephritis, from 111½ to 93½; from organic heart disease, from 91½ to 87; from typhoid fever, from 9½ to 7½, and from influenza, from 4¾ to 1¼. During the last week in June, for the first time since early in the autumn, no death was reported from influenza. Almost the only affections in which there was an increase in mortality were the diarrheal diseases. The weekly average of deaths from these increased from 44¼ in May to 82¼ in June; and the weekly average from diarrheals in children under two years, from 44¼ to 82¼. Doubtless on account of the remarkable coolness of the weather during the month of June, this increase is smaller than usual for the season.

APPOINTMENT OF DR. R. M. PEARCE. — Dr. R. M. Pearce of Philadephia has been appointed as the successor of Dr. George Blumer in the faculty of the Albany Medical College, as adjunct professor of pathology and bacteriology, and director of the Bender Hygienic Laboratory. Dr. Pearce is to assume the position on Sept. 1, when Dr. Blumer retires, and his assistants will be Drs. E. McD. Stanton of New York and Charles K. Winne of Mount Wilson, Maryland.

APPROPRIATIONS. — At the meeting of the Board of Estimate and Apportionment on July 1 a number of important appropriations were made. Among these were $638,000 to acquire sites and construct public baths in Manhattan; $211,600 for two baths in the Greenpoint and Navy Yard sections of Brooklyn, and $155,000 for baths in the Bronx. This last is to be applied to the construction of three baths, one of which will be a permanent building for use throughout the year. At this meeting the board authorized the condemnation of additional land for the new Bellevue Hospital. This is to take in the block between First Avenue and the East River, which lies immediately north of the present hospital buildings. Issues of stock to the amount of $175,000 and $100,000, respectively, for the Zoological Park and the Botanical Gardens in the Bronx, were also authorized.

DEATHS AND BIRTHS IN 1903. — During the first six months of 1903, 34,855 deaths were reported in the city, representing an annual death-rate of 18.67, against 35,491 deaths in the first six months of 1902, with a death-rate of 19.54. The births reported numbered 46,408, against 40,392 for the first half of 1902.

HOSPITAL FOR CONVALESCENTS. — A new departure was made on July 1 by the department of public charities in opening a hospital for convalescent patients. The building used for the purpose is at the northern end of Blackwell's Island, and was formerly occupied by the Manhattan State Hospital for the Insane. It contains forty beds for men and thirty for women; and the number of these may be increased, with an increased demand, up to seventy-five for men and sixty for women. Patients will be allowed to remain for three weeks under ordinary circumstances, and for six weeks in exceptional instances.

STATE DEATH-RATE. — The monthly bulletin of the State Health Department, issued July 2, shows that the death-rate in the State declined from 16.8 in April to 16.1 in May. In the month of May pneumonia caused 1,084 deaths, a daily average of 35, against 40 in the first three months of the year. Influenza was credited with about 1,000 deaths, or 200 less than in April. Smallpox caused three deaths, all in Rochester, but no new cases had been reported there since May 25. At Elmira and Dansville cases of the disease were reported which originated from recently detected outbreaks in towns in Livingstone County, where smallpox has made considerable headway.

PRIZES FOR CLEAN TENEMENT HOUSES. — An interesting feature of the annual meeting of the East Side Janitors' Society at the Educational Alliance Building, on July 2, was the presentation of money prizes, medals or diplomas, for keeping their tenement houses clean, to 37 out of a total of 130 contestants. In making out the awards the points considered included each particular part of the premises. Mr. De Forest, president of the Tenement House Department, was one of the speakers on this occasion, and in the course of his remarks said that if the members of this association could be got to teach the other janitors of New York to do the same laudable things which they were endeavoring to accomplish, there would be no need of any tenement-house inspection.

TETANUS GERMS IN BLANK CARTRIDGES. — It is reported that tetanus germs have been discovered by Dr. Richard N. Connolly, bacteriologist of the health department of Newark, N. J., in blank cartridges offered for sale in that city. It is stated that Dr. H. C. Herold, president of the department, had suspected the existence of the bacilli in blank cartridges for some time, and that his suspicions were greatly strengthened by the reports of a recent outbreak of tetanus in Pittsburg, in which fifty cases are said to have followed a celebration in which firearms were used. He therefore called the attention of Dr. Connolly to the matter, and in consequence of the discovery by the bacteriologist a special meeting of the Board of Health was held on July 2 to adopt suitable measures to protect the community.

BURNING OF AN ISOLATION HOSPITAL. — The main building of a group erected in Orange, N. Y., at the time of the smallpox outbreak about two years ago, and used since then as an isolation hospital, was destroyed by fire on July 2, and it is believed that the fire was an incendiary one. Considerable difficulty was experienced in finding a location for the hospital, and in consequence of the objections of neighboring property holders the buildings were shortly to have been removed to the Orange poor-farm.

NOTES FROM THE PHILIPPINES.

MANILA EXHIBIT AT ST. LOUIS EXPOSITION. — The Board of Health of Manila is preparing to make an elaborate display at the St. Louis Exposition, and a committee consisting of Dr. E. L. Munson, U. S. A., assistant to the Commissioner of Health, Mr. A. Jadin, sanitary engineer, and Dr. Arlington Pond, medical inspector, has been appointed to prepare the exhibit. The sum of $1,000 has been appropriated to meet the expenses of the exhibit and 250 feet of wall space and 150 feet of floor space allotted for its display. The exhibit will be very complete, and is especially intended to show the good results attending the American con-

trol of sanitary matters in these islands. As far as possible in the photographic exhibit, conditions as they existed before and after the Americans took hold of affairs will be shown. The exhibit will show the results of an efficient sanitary administration, and will undoubtedly prove not only interesting but instructive to visiting sanitarians and others as illustrating the obstacles which it has been necessary to overcome.

The exhibit will include a complete file of all the publications, reports, circulars, blank forms and other printed matter issued by the Board of Health. There will be a number of maps and charts having to do with the distribution and prevalence of the most important diseases, and their prevalence among the different classes and races in the population of Manila. The photographic exhibit will include large photographs, more than one hundred in number, illustrating every phase of the work of the Board of Health in Manila. The subjects of streets, habitations, hospitals, drainage, sewerage, disposal of excreta, food and water supply will be fully illustrated, and special attention given to the subjects of cholera, plague and leprosy and the measures being taken for their prevention. Animal diseases and their prevention will be given much space. All in all, the exhibit will be very complete, and will probably compare most favorably with the showing made by other cities. It is felt that the situation and conditions here have not been fully understood, and the Board of Health proposes to show not only what has been accomplished, but the sanitary obstacles which have been overcome.

EXHIBIT FROM PATHOLOGICAL LABORATORY.— The Pathological Laboratory will also make an exhibit, which, though small, will be very instructive. Particular attention will be paid to the subjects of plague, cholera, leprosy, surra and the animal parasites of the Philippines. The laboratory has a wealth of pathological material, which it is proposed to work up as fully as possible, and exhibit in the form of gross and microscopical specimens, photographs, photomicrographs and tube and plate cultures. This exhibit should be of much value to those interested in the study of the diseases of the tropics.

CHOLERA.— In view of the development of a few cases of cholera daily in Manila, the health authorities have caused 30,000 circulars in Tagalog and 5,000 in Chinese, containing a few simple rules for the prevention of cholera, to be printed. One of these circulars will be posted with the sanitary card in every house in the city, and will also be placed in every casco, lorcha and other inhabited watercraft in the bay and river.

PREVALENCE OF CHOLERA. — Since the beginning of the year to May 25, there have been 242 cases of cholera in Manila, with 208 deaths, 7 recoveries and 27 cases under treatment. The disease has been practically confined to those whose occupations keep them along the waterfront, such as sailors, boatmen, fishermen, laundresses, etc. There is no question but that the Pasig and its esteros are infected, but it is a most difficult matter to prevent the natives from acquiring this infection. They bathe, wash their persons and utensils in the water, and probably in some cases use it to drink, in spite of every effort by the health authorities for the prevention of such practices. A considerable part of the population of Manila lives on boats, and at night-time it is practically impossible to prevent breaches of the sanitary regulations by this class. That a certain proportion of the cases of cholera occurring on these water craft are successfully concealed is evident from the considerable number of "floaters" dead from cholera which are removed from the river. A few cases of the disease seem to be traceable to the use of infected foods, but how this food question may be solved without bringing the low-class natives almost to the verge of starvation has not yet been apparent. All food offered for sale in the markets is carefully inspected, and any that is of doubtful character is rigorously condemned and destroyed; but it is not difficult to imagine how apparently good food may harbor the cholera germ and still pass muster with the inspector. A bacteriological examination of every article of food, or its disinfection, is quite out of the question, and all that can be done is to do the best possible under the circumstances. That the measures employed are reasonably efficient is shown by the fact that last year at this time there were fifty or seventy-five cases a day, while this year, with the same infection, there are probably not a half-dozen cases a day. Last year, however, a third of those attacked survived, while this year the disease has manifested a highly virulent character, and nearly all those who contract the disease seem to die in a few hours. Of the first couple of hundred cases during the present year, more than 90% died; of 54 consecutive cases 51 succumbed. The last week or so, however, the disease appears to have become milder in type. So far, the water supply of Manila has not become infected, and every possible precaution is being taken to prevent such contamination. Should the water supply become infected, the mortality in Manila, with the present virulent infection, would be very great.

THE PLAGUE SITUATION. — The plague situation at the present time shows very marked improvement. There were 17 cases in February, 42 in March, 52 in April, and only 24 up to May 27. This im-

provement is unquestionably due to the great activity of the health authorities in operating against plague; as in Hong Kong the plague has increased rapidly by leaps and bounds, and there were 117 cases in that city for the week ending May 16. In spite of the fact that Manila has a larger population than Hong Kong, and that the local conditions are here apparently more favorable to plague than in the latter city, Hong Kong has had about as many cases of plague in one week as Manila has had in three months. The plague mortality here has so far been 118 deaths out of 136 cases, with 9 recoveries and 9 cases remaining under treatment. The reduction in the number of plague cases is undoubtedly due to the stringent measures which are being enforced. Rats are being caught by the corps of rat catchers at the rate of about 12,000 a month, besides those poisoned, killed on the shipping and destroyed by property owners. Plague houses are carefully disinfected and repaired, or destroyed by fire. The most efficient measure of prevention is undoubtedly to be found, however, in the inoculation of every one of the 60,000 Chinese in the city with Shiga's plague prophylactic. This invention is being carried out systematically, house by house, street by street and district by district. All the Chinese are brought to the sanitary stations and inoculated, and this inoculation is repeated in ten days or two weeks. Those who are unable to call at the stations by reason of infirmity or illness are inoculated at their houses; such as choose, may employ private physicians approved by the Board of Health. Chinese women are inoculated at their homes by a trained female nurse. So far, there have been no untoward results whatever as a result of inoculation, and the local reaction is not sufficient to cause serious discomfort. That the measure is efficient is shown by the fact that no case of plague has occurred among the inoculated, while in a number of cases it has happened that the only uninoculated Chinaman in a large household has contracted the disease. The Chinese themselves see the efficiency of the process, and submit to it without opposition.

While the task of inoculation seems to be a mammoth undertaking, each sanitary station has a complete list of all the Chinese in its district, the location of their homes and data for identification. If a Chinaman leaves the district or takes up a new residence the health authorities must be notified. With such wholesale inoculation and rat catching the health authorities hope that the present year may see the last of the present infection in Manila. The proximity of China, however, implies special vigilance by the quarantine officials to prevent the importation of a new infection.

The Board of Health has also issued a plague circular in English, Spanish, Chinese and Tagalog, calling attention to the importance of rats as carriers of the plague infection, and the necessity of their destruction in combating the spread of the disease. All householders are urged to co-operate with the official rat catchers in the destruction of the rodents, and public notice given of the bounty to be paid for all rats delivered at Board of Health stations. The importance of sanitary surroundings and personal hygiene is also dwelt upon in the prevention of plague, together with the importance of early reporting cases of a suspicious nature to the Board of Health.

STATUS OF CHRISTIAN SCIENCE. — The attorney-general for the Philippine Islands has lately acted on a request from the Board of Health for information as to whether Christian Science healers could be prosecuted under the laws governing the practice of medicine in the Philippines. The law provides that those who "operate, prescribe, treat or advise" patients for a fee shall be regarded as engaging in medical practice, and restricts such practice to graduates of medicine who have passed the board of medical examiners, or who registered as practitioners of medicine prior to March, 1902. The attorney-general quotes extensively from the decisions in various states of the United States, relative to the status of Christian Science, which he regards as not finally determined. While the weight of evidence tends to permit the practice of Christian Science in the United States, the attorney-general states his personal belief that the practice of Christian Science constitutes the practice of medicine, and as such comes under the laws regulating the practice of medicine in the Philippines. He states, however, that this question is one for the courts to decide.

METEOROLOGICAL RECORD.

For the week ending June 27, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

Deaths reported, 2,934; under five years of age, 1,031; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 867, acute lung diseases 298, consumption 340, scarlet fever 39, whooping cough 29, cerebrospinal meningitis 9, smallpox 5, erysipelas 6, measles 31, typhoid fever 44, diarrheal diseases 275, diphtheria and croup 78.

From whooping cough, New York 4, Chicago 7, Philadelphia 8, Baltimore 4, Providence 1, Boston 1, Cambridge 1, Holyoke 2, Brockton 1. From erysipelas, Chicago, Philadelphia, Baltimore, Boston, Cambridge and Newburyport 1 each. From smallpox, Chicago 1, Philadelphia 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending June 13, the death-rate was 13.9. Deaths reported, 4,022; acute diseases of the respiratory organs (London) 141, whooping cough 76, diphtheria 56, measles 124, smallpox 13, scarlet fever 39.

The death-rate ranged from 4.7 in Hornsey to 25.1 in Great Yarmouth: London 12.4, West Ham 12.8, Brighton 11.6, Portsmouth 13.1, Southampton 9.9, Plymouth 11.2, Bristol 12.8, Birmingham 14.8, Leicester 9.2, Nottingham 15.1, Bolton 15.9, Manchester 16.8, Salford 15.9, Bradford 14.4, Leeds 15.3, Hull 1.52, Newcastle-on-Tyne 15.7, Cardiff 12.4, Rhondda 16.1, Liverpool 19.3, Sheffield 18.6.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JUNE 25, 1903.

GASSAWAY, J. M., surgeon. Granted leave of absence for two days from June 7. June 19, 1903.

WASDIN, EUGENE, surgeon. Granted leave of absence for three days from June 20. June 25, 1903.

BROOKS, S. D., surgeon. Granted leave of absence for one day, June 22. June 25, 1903.

WHITE, J. H., surgeon. Granted leave of absence for one month from July 2. June 25, 1903.

CARRINGTON, P. M., surgeon. Six days' leave of absence, under paragraph 189 of the regulations, from June 20, 1903. Granted extension of leave of absence for 7 days. June 23, 1903.

YOUNG, G. B., passed assistant surgeon. Granted leave of absence for two months from July 7. June 22, 1903.

SPRAGUE, E. K., passed assistant surgeon. Leave of absence for seven days from June 4, 1903, granted Passed Assistant Surgeon Sprague under paragraph 191 of the regulations, amended so as to be for four days only.

Relieved from duty at Fort Stanton, N. M., and directed to proceed to Calcutta, India, for duty in the office of the U. S. Consul-General. June 25, 1903.

GRUBBS, S. B., passed assistant surgeon. Granted extension of leave of absence for seven days from June 23. June 18, 1903.

GWYN, M. K., assistant surgeon. To report to Assistant Surgeon V. G. Heiser, recorder of board of examiners, Manila, P. I., on August 8, 1903, for examination to determine his fitness for promotion to the grade of passed assistant surgeon. June 20, 1903.

HOBDY, W. C., assistant surgeon. To report to Passed Assistant Surgeon L. E. Cofer, recorder of board of examiners, Honolulu, T. H., on August 15, 1903, for examination to determine his fitness for promotion to the grade of passed assistant surgeon. June 20, 1903.

EARLE, B. H., assistant surgeon. Granted leave of absence for seven days from June 25. June 23, 1903.

BREADY, J. E., acting assistant surgeon. Leave of absence for three days granted Acting Assistant Surgeon Bready by Bureau letter of June 6, revoked. June 22, 1903.

HARRIS, B. Y., acting assistant surgeon. Granted leave of absence for thirty days from July 22. June 22, 1903.

SWEETING, C. B., acting assistant surgeon. Granted leave of absence, on account of sickness, for thirty days from June 10. June 18, 1903.

ILTIS, G. W., pharmacist. To report to Passed Assistant Surgeon W. G. Stimpson, chairman of board of examiners, San Francisco, Cal., on June 29, 1903, for examination to determine his fitness for promotion to the grade of pharmacist of the second class. June 22, 1903.

BOARDS CONVENED.

Board convened to meet at Washington, D. C., June 25, 1903, for the preparation of sketch plans and memoranda relative to a hospital building at Ellis Island N. Y. Detail for the board: Assistant Surgeon-General L. L., Williams, chairman; Assistant Surgeon General W. J. Pettus; Surgeon G. W. Stoner; Passed Assistant Surgeon J. C. Perry, recorder.

Board convened to meet at San Francisco, Cal., June 29, 1903, for the examination of Pharmacist G. W. Iltis, to determine his fitness for promotion to the grade of pharmacist of the second class. Detail for the board: Passed Assistant Surgeon W. G. Stimpson, chairman; Assistant Surgeon C. W. Vogel, recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JULY 4, 1903.

J. T. MILLER, acting assistant surgeon. Detached from recruiting duty; and ordered home to wait orders.

R. B. CHAPMAN, acting assistant surgeon. Detached from recruiting duty, and ordered home to wait orders.

D N. BERTOLETTE, medical inspector. Ordered to Washington, D. C., as member of the Naval Medical Examining Board.

J. A. MURPHY, assistant surgeon. Detached from the "Monadnock," and ordered to the "Celtic."

R. K. MCCLANAHAN, assistant surgeon. Detached from the "Oregon" and ordered to the "Villalobas."

RECENT DEATHS.

Henry Melville Chase, M.D., M.M.S.S., died in Lawrence, June 15, 1903, aged sixty-five (65) years.

BOOKS AND PAMPHLETS RECEIVED.

An English Handbook of the Paris Medical School. By A. A. Warden, M.D., with Prefatory Letters by Lord Lister and Prof. W. W. Keen. Philadelphia: P. Blakiston's Son & Co. 1903.

Address.

THE SHATTUCK LECTURE.

THE SOURCES, FAVORING CONDITIONS AND PROPHYLAXIS OF MALARIA IN TEMPERATE CLIMATES, WITH SPECIAL REFERENCE TO MASSACHUSETTS.*

BY THEOBALD SMITH, M.D., OF BOSTON.

INTRODUCTORY.

AFTER I had accepted the honor of addressing you this evening as Shattuck lecturer, several topics of great interest to me presented themselves. After carefully considering them in the light of the provisions of the Shattuck bequest, it seemed to me that a discussion of malaria, with special reference to our own State, would at this time be the most useful. I accepted this self-imposed task the more willingly as since 1895 I had been giving much time during the summer months, under the auspices of the State Board of Health, to the study of malaria and the local conditions favoring it. Most of the facts I have personally gathered we owe to this board; for without their active co-operation the topography of the disease could not have been investigated.

If we were to depict the dissemination of malaria, this scourge of an invasive and militant civilization, upon the globe, we would paint it as a black belt girdling the tropical world and extending its lesser shadows in tongues toward the temperate zones. These shadows become less and less distinct the farther north we go. Though the harm it does to northern civilization is infinitesimal compared with its almost forbidding attitude in the tropics, yet even with us the energy needed for the ceaseless struggle for existence suffers severely when malaria is invading the blood, the integrity of which is so essential to our well-being.

Many things have conspired to bring about a renewed public interest in this disease. First and foremost the stimulus created by the colonial expansion of European nations, next the conditions which paved the way for a scientific demonstration of the existence of an intermediate host or carrier in the mosquito, and lastly the tendency of the intelligent classes in our climate toward suburban and rural homes and the general quickening of all interests in animal and plant life, have enlisted not only the attention of the public but their material support for the suppression of conditions favoring malaria. These various interests are perhaps a sufficient excuse for dealing with the newer aspects of this subject on this occasion. But the greater stimulus to me has been the fact that malaria is a prevalent disease of our State, that it has for us a decidedly sanitary as well as economic bearing. Some overworked and apathetic practitioners in rural communities may perhaps say, "What have the newer developments in regard to malaria to do with us? We can cure tertian fever with quinine and we can with equal readiness cure any relapse." This is true as far as it goes; but it would be a very narrow view to take and would, I feel sure, be spurned by our society as unworthy of its past record and future promise. There is, however, a concealed, or at least overlooked, misinterpretation here which I cannot pass over in silence.

Medicine's legitimate field of work is not only sickness but health. Medical science has been moving the pivotal point of successful combat with disease more and more toward the well man. Hence we have the two great departments of the medicine of to-day, the curative and the preventive. The latter, the latest to develop, is yearly growing in importance and will eventually overshadow the former; for it is based on sounder biological and economic principles. Preventive medicine acts in an entirely different way from curative medicine. The latter saves its patient here and there and its services are conspicuous and positive, but the former works only collectively in a negative way and its services are inconspicuous. It also saves lives and prevents disease, but only through cold and dry statistics can it lay any claim to its achievements. It works by slow increments. Like the builder's screws which, placed under a building, raise it through an inappreciable distance each day, so preventive medicine slowly raises the sanitary level, and the total aggregate of all the inappreciable increments means many lives saved and much illness prevented. The study of malaria and the application of the principles underlying it mean no new cures, but a steady elevation of the healthfulness of rural life, the only source of a robust generation.

My task was finally made still easier from the observation I have made frequently of late that among many physicians, engineers and educated people generally, the mosquito has as yet no assured position as a transmitter of the malaria parasite. If our recent developments are to have much value, they must be applied at once, the principles must be made operative and enter intimately into the life of rural populations. We have become now fully cognizant of the hurtfulness of sewage out of place and of sewer gas. In fact our legislative sensitiveness to sewer gas became so great that both capital and labor trusts are said to batten on the severe restrictions created by it. Of now much more definite significance in pathology than sewer gas is the malaria organism! But the history of sewer gas legislation shows what can be done if the public interest is once aroused. Fortunately, the prevention of malaria does not demand such artificial measures as are in use against sewer gas, but only such as will add permanently to the utility and beauty of the land.

THE LIFE CYCLE OF THE MALARIA PARASITE HISTORICALLY AND BIOLOGICALLY CONSIDERED, WITH SPECIAL REFERENCE TO PLASMODIUM VIVAX, THE PARASITE OF TERTIAN MALARIA.

The proper presentation of my subject demands at the outset a very brief *résumé* of the main facts of malaria as known to-day, so that we may be able clearly to apprehend the application of these facts in the framing of preventive measures. The development of our positive knowledge of malaria etiology may be divided into two periods. The first embraces the period from 1880 to 1895 and is chiefly concerned with the study of the malaria parasite in human blood and the clinical interpretation of its

* Delivered before The Massachusetts Medical Society, June 9, 1903.

various appearances. The second period, extending from 1898 to the present, is concerned chiefly with the sexual reproduction of the parasite in the mosquito and with many questions of immunity and epidemiology.

The facts elucidated during the first period may be considered as already common property of the profession. They are included in all text-books on clinical medicine. All students who graduate from first-class medical schools are able to recognize malaria parasites and are prepared to make a diagnosis with the aid of suitable microscopes and accessories. Even many older practitioners have prepared themselves to do the same thing.

A detailed account of the discoveries of this first period would thus be superfluous; but I cannot refrain from mentioning the more important stages in its history, if only as a fresh acknowledgment of the arduous labors of those who were the important contributors. For this first period the excellent detailed historical *résumé* given by Thayer and Hewetson [1] should be consulted by all those interested in the laborious progress of science as well as its immediate achievements. To it I must also refer the student of malaria for a full bibliography to 1895.

In 1880 the parasite of malaria was first recognized as such by Laveran, then a French military surgeon stationed in Algiers. In 1885 Marchiafava and Celli in Italy pointed out the possible significance of the segmenting bodies as reproductive phases in the life-cycle of the parasite and insisted upon the fact that the parasites were within the corpuscles and not merely attached to them as Laveran maintained. In the same year (1885) a new observer appeared upon the field in Italy whose researches were, next to those of the actual discoverer of the parasite, the most important as bearing upon the parasite in the blood of man. Golgi described in detail the growth of the microorganism of quartan fever and some years later that of tertian fever. He points out differences between these two parasites at various stages in their growth and first definitely associates the segmentation with the paroxysm. He shows that quotidian fevers are due simply to two or three groups of parasites maturing on different days. Henceforth the microscope would enable the skilled observer to make a diagnosis between tertian and quartan fever, to recognize quotidian types and to approximately fix the time of the paroxysm. This great advance did not include in its scope what we now know as the more dreaded estivo-autumnal or tropical fever, a type of malaria practically unknown in New England, excepting as it may be imported in isolated cases. Councilman was one of the first to insist upon the association of certain forms of parasites with the more irregular and continuous fevers. In 1889 Marchiafava and Celli and Canalis headed a long series of investigations upon this third type of fevers. This is not the time to recount the many shades of opinion, the many and diverse classifications into distinct varieties of the estivo-autumnal type as the result of laborious investigations. In brief, it may be stated that the tendency is to regard the varieties of this third type of fever as a unity to-day.

With the middle of the last decade the study of the malaria parasite in the human body seems to have exhausted itself. As is the case where the microscope is the only tool, interpretation is difficult; and there is always danger in the framing of hypotheses from what we see that we may put the cart before the horse, as either method usually satisfies appearances. The stimulus which was to bring renewed life into this subject came from several different directions and with their aid the end the century saw revealed one of the most interesting biological phenomena, in which three different organisms combined to complete what is in many respects a most vicious circle for one of them. The second period presents a congestion of interesting details from several distinct sources. These details are not yet widely known, and an historical survey would be misleading. The simplest method which presented itself to me was to give a very concise sketch of the tertian parasite as it is known to us to-day and then refer briefly to the sources contributing the fertile hypotheses.

The parasite of tertian fever in its earliest stages appears within the red corpuscle either as a small ring or as a body consisting chiefly of slender filamentous prolongations or pseudopia. Examined fresh, it exhibits ameboid movements most active at the temperature of the blood. Soon reddish brown pigment granules begin to appear which increase in number with the size of the parasite. Before the end of forty-eight hours the parasite has grown as large as the host-cell, and the latter may be still seen in faint outline or it may have completely disappeared. At this time signs of segmentation appear. The pigment tends to gather into a more or less compact mass in the center, and the parasite separates into from twelve to twenty-four small nucleated bodies, the so-called spores of the older writers, the merozoites of the present. These small bodies again enter red corpuscles, where the same process is passed through to the stage of segmentation or schizogony. The latter is associated with the paroxysm as already determined by Golgi.

This process of asexual reproduction is the one which is mainly responsible for the symptoms of disease. It destroys red corpuscles, and the fever induced may be due either to the corpuscular débris or perhaps more reasonably to the foreign substance of the parasite set free or left behind when the merozoites break away from the mother parasite to begin life anew.

After a certain time, as yet indefinitely known, the process takes another direction. The young merozoites, after entering red corpuscles, instead of growing into the segmenting bodies described above, develop into forms which closely resemble those bodies, but which do not segment. They are the male and female elements concerned subsequently in the body of the mosquito with sexual reproduction. The female body is known as macrogamete, the male as microgametocyte. These three individuals, the segmenting body or schizont and the male and female bodies, have been recently distinguished from one another by Bastianelli and Bignami,[2] Grassi,[3] and more in detail by Schaudinn,[4] who gives a number of differential characters pertaining to the structure of the nucleus, the cytoplasm, pigment, vacuole, and time of growth

of the sexual and asexual individuals. In other words, with proper methods of fixation and staining the skilled observer can determine at an early stage of the intra-cellular parasite to what cycle it belongs.

Leaving aside as somewhat beyond the scope of this lecture the characters of the sexual elements or gametes, I may simply state that they develop into bodies which slightly exceed those of the adult schizonts. While the latter rarely exceed 10 mm., according to Schaudinn, the former may become 12 to 16 mm. in diameter. When they have reached this stage no further changes occur until they have been drawn into the mosquito's stomach. It should be stated, however, that when freshly drawn blood is watched, further changes do occur in the male body, which consist in the extrusion of spermatozoa or microgametes, the so-called flagella of earlier writers. This extrusion is brought about by conditions simulating those in the stomach of the mosquito.

The life cycle of the malaria parasite thus comes to a standstill in the blood of man, after a certain time to be completed in another host. In the blood drawn into the mosquito's stomach the two sexual elements or gametes rapidly complete their development. The male element extrudes four to eight flagellate bodies or microgametes, which are from $2\frac{1}{2}$ to 3 times the diameter of a red corpuscle in length. These move and lash about actively, tear themselves away from the parent body, and move through the fluid. One of these penetrates into a macrogamete. This process of fertilization is similar to that of higher forms. The male element, composed largely of nuclear matter, unites with the nuclear matter of the female element to form a new nucleus.

The fertilized female body after about ten minutes begins to push out a hyaline prolongation, which gradually grows until the entire body has assumed a wormlike form. This little worm (oökinet) begins at once to seek its future abiding-place where it is to produce the countless infecting sporozoites. It penetrates the epithelial layer of the stomach and comes to rest beneath the external elastico-muscular tunic of this organ. In this situation the parasite slowly goes larger, and as it grows bulges the external tunic of the stomach, which forms its envelope, outward into the body cavity. Up to five hundred of such bodies may, according to Grassi, develop the stomach walls of a single individual. Their final size varies more or less according to external temperature and food supply. During the enlargement of these bodies profound internal changes are under way. The fused nucleus of the original oöcyst undergoes repeated division. The new nuclei become the centers of irregular masses, the sporoblasts. Each new nucleus again subdivides into an indefinite number of minute nuclei, which appear on the periphery of the irregular masses, or sporoblasts, and there, by gathering about them cytoplasm, they eventually form the myriads of fusiform bodies known as sporozoites. These when mature become detached from the mother mass, and when the cyst bursts they enter the body cavity. They are very slender bodies, on an average 14 mm. long and between 1 and 2 mm. wide in the middle. They possess the power to change their form as well as to move. After their discharge into the body cavity, some attraction draws them to the salivary glands, which they penetrate and where they imbed themselves in the secreting cells and in the lumen of the gland.

These slender mobile organisms (sporozoites) are discharged into the blood of man when the proboscis of the infected mosquito penetrates the skin and reaches a vessel. Schaudinn recently described the entry of two of these bodies into red corpuscles as observed by him through the microscope. Within the red corpuscle each body begins the life cycle anew.

The time required for the formation of sporozoites in the mosquito varies with the temperature. According to Grassi the shortest period is about ten days. Allowing, according to the same observer, about ten days between inoculation by the mosquito and the appearance of the fever, at least twenty days would elapse after a mosquito had become infected before another case would appear.

We have now sketched, in bare outlines, the life cycle of the malaria parasite and with it the mode of transmission of the disease from man to man. As I stated before, the unraveling of this wonderful chain of events was not accomplished by one man, but a number of contributors have assisted in interpreting this wonderful bit of parasitism.

The germs of hypotheses concerning the mosquito have been traced well back.* In 1882 A. F. A. King advocated the mosquito theory on the basis of general epidemiological facts.

Manson, in 1894, declared for the mosquito as transmitter. The mosquito draws the parasites into its body with the blood. There spores are formed and when the mosquito dies they are shed broadcast in the air and the water, and we become infected when we inhale or ingest them. His hypothesis was evidently suggested by his important work on Filaria.

In the experimental studies upon the malaria of cattle, known popularly as Texas cattle fever, the writer,[5] in association with F. L. Kilborne, after four years of nearly continuous investigation arrived at certain conclusions in 1893 which have been the forerunners of the well-established principles governing human malaria.

The blood parasite in this affection lives within the red corpuscles. The ectoparasite which draws it out of the body is the Southern cattle tick (Boöphilus bovis, Curtice). But the process of transmission is more complicated than that for malaria discovered over five years later. The mother tick which draws the blood and in it the parasite into her body never attacks another animal. After having gorged herself with blood designed for the nourishment of the ova, she drops to the ground, deposits a large number of eggs, and dies. The young larvæ, emerging from the eggs after three or four weeks, attach themselves to cattle, and in doing so inoculate the blood parasites transmitted to them by their mother. It will thus be seen that nature had to provide for the infection of an unborn generation of ticks in the body of the mother tick in order to have the

* For a full historical résumé, including bibliography, we are indebted to George H. F. Nuttall. — Johns Hopkins Hosp. Rep., Vol. viii

malaria parasite transmitted to other cattle. When this complicated mechanism for the transfer of a minute blood parasite came to light after two years of experimentation, it seemed so wonderful that it staggered my belief in the etiological rôle of the bovine malarial parasite, and new experiments had to be tried to make this wonderful mechanism credible. The malarial organism was soon rehabilitated, however, when we found that the disease could be produced without the aid of the cattle tick by simply inoculating with the blood of cattle carrying it. It could also be shown that the disease could be produced at a distance by simply importing adult female ticks from an infected locality, breeding the larvæ from the eggs and putting them on susceptible cattle. I speak of these experiments because they completely refute the hypothesis occasionally presented that the mere sting or bite can produce disease by a process akin to poisoning and because they illustrate the symbiosis existing between the cattle and the blood parasite on the one hand and the blood parasite and the cattle tick on the other.

Here we have the first actual demonstration that ecto-parasites drawing blood inoculate the virus when they sting. It remained too strange a fact to be properly accepted, but it slowly began to stimulate students of human malaria, as shown in their references to the implied analogy. Notably the Italians were impressed with it, and without doubt the fact that Koch,[22] in 1898, was able to repeat and confirm the experiment upon cattle in Africa led him to attack the malaria problem with his usual energy. In the meantime Ross, [6] working in India, had, in 1898, practically worked out in certain mosquitoes the cycle of bird malaria, which subsequently proved to be nearly identical with the cycle as observed in human malaria. Ross is therefore the one to whom the credit for demonstrating the malaria cycle belongs.

But there were other contributing sources which were essential to an understanding of the significance of certain forms of the malaria parasite. Since Laveran's discovery in 1880 it was known that certain large forms of the malaria parasite, when the blood containing them was watched under the microscope, extrude four or more delicate filaments which are actively motile for a time. There were also the peculiar crescent-shaped forms in the blood in the tropical fever which puzzled observers. Both the flagellate and the crescent forms were variously interpreted as degenerations and their significance wholly misunderstood. In 1897 McCallum [7] in the study of bird malaria grasped the true significance of these forms when he saw under the microscope the flagellum of one form penetrate into another.

The sexual process here observed at once gave a new significance to these neglected, misinterpreted flagellate bodies, and to the crescents which we now know as the gametes, and which carry on the life of the malaria parasite in the mosquito. At the same time studies by Simond [8] in France on related sporozoa, known as coccidia, revealed the presence of peculiar structures which were speedily identified as male sexual bodies. These two converging lines of experimentation, the demonstration of the transmission of malarial disease by the prick of arachnids in cattle and by mosquitoes in malaria, and the disclosure of sexual phenomena in the malaria of birds and in the coccidia, enabled such skilled observers as Grassi in Italy, Koch in Italy and the tropics, Ross in India, and a host of others, to perfect the details of proof and give them weight before the uninitiated and incredulous multitude of professional and lay lookers-on.

There remained still one problem to be disposed of. The universality of the mosquito and the restricted areas of malarial infection are so clearly opposed to one another that the new facts could hardly be expected to make headway without further work. The many species of mosquitoes, rising into the hundreds, cannot all be concerned in this vicious circle. To Grassi more than to any other belongs the credit of having called attention to the genus Anopheles as the intermediate host of human malaria. So far, there seem to have been no developments to contradict Grassi's work. Not only he, but the English malaria expeditions, and quite recently Schüffner,[9] have traced the parasite of human malaria through certain species of Anopheles. At the same time it is not to be inferred that all species of Anopheles are necessarily carriers, as I shall point out later on, and that in any locality the prevailing species should be tested with reference to this point.

It is interesting to note that one kind of bird malaria (*Proteosoma*) seems to be transmitted by certain species of Culex. Of the other widely distributed form of bird malaria (*Halteridium*), the intermediate host remains unknown.

It would be idle for me to assert that with the discovery of the sexual cycle of the human parasite in Anopheles all the vexed questions concerning the epidemiology of malaria had been disposed of. On the contrary, we have just begun to appreciate the sure footing gained and we must now begin to study those elusive variations in the disease due to latitude, climate and seasons, and to racial diversities, without which practical measures for the eradication of malaria from any given territory can have but little assurance of ultimate success. It is with special reference to these many variable factors that I venture to present the subject to-night.

THE RELATION OF THE TERTIAN PARASITE TO THOSE OF THE QUARTAN AND THE ÆSTIVO-AUTUMNAL OR TROPICAL FEVER.

It is now well known that there are three species or morphological types of malaria parasites. The tertian and quartan parasites were first distinguished by Golgi, the estivo-autumnal somewhat later. The distribution of these three forms and the existing controversy whether they are distinct species or manifestations of but one under different conditions, bring them necessarily within the scope of our subject.

Concerning their distribution it may be briefly stated that the estivo-autumnal or tropical parasite has its home chiefly in the tropics, and extends thence into the adjacent belts of the temperate zones. The quartan parasite has nearly the same distribution, but it is only rarely encountered. The tertian parasite is more cosmopolitan. It is found both in the tropics and in the temperate zones.

A majority of observers are agreed that the three forms are distinct, while a minority are of the

opinion that the three forms really represent one species and that a different environment and perhaps different degrees of immunity account for the different forms. This is not the place to enter into a description of the three types or forms. Good descriptions will be found in Thayer and Hewetson[1], Ewing[10], Ruge[11], and others. Suffice it to state that certain differences between them are thoroughly well established. Among them are the crescents (gametes) of estivo-autumnal fever which are not found in tertian and quartan fevers. The tertian parasite attains a larger size than the quartan, and the red corpuscle is swollen and pale. In the segmenting stage twelve to twenty (Thayer), or fifteen to twenty-five (Ruge), spores (merozoites) are set free, whereas in quartan infections only six to twelve spores are formed. There are also differences in the form of the pigment.

The estivo-autumnal parasite differs from the tertian and quartan not only in the presence of crescents, but also in the absence of sporulating forms in the peripheral blood. The forms there found are rings, at first very minute, then larger. These finally disappear. The segmenting stages are found in the spleen, bone marrow, brain, etc. These differences, and others not mentioned, upon which observers working in different continents on the whole agree, appear sufficient to justify the establishment of three species of malaria parasites. Yet there are good reasons for not considering them impregnable. Assuming for the moment that they are independent organisms, we must meet the interesting fact that in our state and in others similarly situated only the tertian parasite is found. In the many specimens from various towns examined microscopically by me and my assistants, the estivo-autumnal species was not recognized as such in any case. Though many soldiers returning from the Cuban campaign brought this form in their blood, no indigenous cases seem to have occurred as a result of this importation. Recently some evidence has been presented to the effect that the estivo-autumnal type of fever is gaining a foothold about New York City. Jackson[12] reports four cases at West Point, only one of which was imported from Cuba. Peabody[13] describes the same disease in a man who during eleven years was only once out of New York. He went to Pennsylvania three years ago and was away four days. Patterson[14] thinks that this type began to appear since 1898.* If we maintain that the estivo-autumnal and the tertian parasites are distinct and independent organisms, we are obliged to support as a corollary one of several propositions: (1) The transmitter of the estivo-autumnal fever is wanting. This is not improbable even with *A. maculipennis* among us; for the crude external species characters may be the same as those in the South, yet the physiology of the insect may be decidedly modified by a colder climate. (2) The mean temperature with us is too low to successfully mature the tropical parasite in the mosquito. (3) The difference in temperature and other meteorological factors are sufficient to repress and suppress this parasite in the blood while we live in this climate. Some of the soldiers who came from the Cuban war affected with malaria showed at first both estivo autumnal and tertian parasites in their blood. Later on the former disappeared and the latter remained, in some cases producing relapses. This disappearance of the graver type of infection and the persistence of the milder type was noticed by Ewing[10] in the military camp at Montauk, N. Y. Does it mean that the soldiers were infected with two parasites at the outset, or did the estivo-autumnal assume the tertian form in the northern climate?

The question is of great interest and importance, yet there is singularly enough no decisive argument which can be applied to definitely settle it one way or the other, although the preponderance of observation and experiment is in favor of the pluralistic view. This has been well summarized recently by Ruge.[15]

CONDITIONS UNDER WHICH THE HUMAN BEING MAY BECOME SOURCE AND CARRIER OF MALARIAL INFECTION.

Our present position as regards the etiology of malaria demands at least two links in the chain of causation. If one is absent the disease must fail to appear. They are:

(1) Infected human beings.

(2) Mosquitoes of the genus Anopheles.

In order to discuss intelligently the relation of human beings to the dissemination of the disease, it will be necessary to recall the fact already described, that in the fresh attack the asexual multiplication of the parasite goes on in the blood for a time. Then sexual forms appear, which, I think, are best interpreted as indicating a beginning of immunity. The mosquito can be infected only through the sexual forms. The important question before us is the relative danger as a source of malaria parasites of the infected person who comes from, or lives in, the region usually free from malaria and of one who comes from a region in which malaria is endemic. An attempt to discuss this complex question requires a brief statement of the new doctrine of acquired immunity in malaria.

This was brought distinctly before us by Koch[16] in the reports of his work in the tropics. The idea that immunity can be acquired toward intraglobular parasites was not new, however. It was shown by myself and Kilborne that immunity is acquired toward bovine malaria, and this fact has been widely exploited in our country to prepare cattle for importation into endemic regions where susceptible animals usually die. In investigations made in East Africa and New Guinea, R. Koch came to the conclusion that malaria is very prevalent in young children, but that it gradually disappears with age and that the adults have acquired immunity. In them the enlarged spleen and other concomitants of malaria have disappeared. A. Plehn[17] disputes the latter as not in harmony with facts, and cities his own studies of the blood of adults as well as the examination of the spleen to show that they too suffer to a considerable degree with malaria. The point I wish to bring out does not concern their controversy, but their essential agreement upon the great prevalence of malaria in children. Plehn, who made careful observations upon this subject, states that, while the youngest children may have numerous parasites in their blood, their

*I subsequently found that Ewing had reported another case in Journ. Exper. Med., 1902, vi, p. 120.

general condition remains undisturbed and temperature elevations are uncommon. The same is true of many adults of whom Plehn found about 50% carrying the malaria parasite without the, to us, familiar clinical disturbances. Christophers and Stevens,[18] in their work under the auspices of the Royal Society of England on the west coast of Africa, in India and other regions in the tropics, find that a large per cent of the native children have parasites in their blood. There is a gradual disappearance with age. After the age of twelve infection is rarely demonstrable. The disease is always mild.*

Annett, Dutton and Elliott[19] of the Liverpool School of Tropical Medicine observed in Nigeria the extensive infection of children. Christophers and Stevens regard this phenomenon of such importance that they base upon the infection of children the prevalence of the disease, or what they call the "endemic index," in any given locality.

Though Koch has been severely attacked for his hastily formed doctrine of immunity, more particularly by Glogner[20] and Kohlbrugge,[21] there can be little doubt that the available data derived from human and comparative sources agree with this doctrine. A distinction should, however, be made between what I prefer to call clinical immunity and biological immunity. An individual may have acquired a considerable degree of biological immunity, but owing to the effort required and the resulting loss of tissues he may come out of the struggle badly off. This must not shut our eyes to the fact, however. In this protean variation of disease, due to the struggle between two variable organisms, we must clearly keep in mind "*Den ruhenden Pol in der Erscheinungen Flucht*," even if it does not always help us cure the patient. The same principle which meets one patient on its downward curve and destroys him, meets another on its upward curve and saves him. We must study the curve and learn where the patient fits it, and where and how to apply assistance.

The general observation in tropical malaria that children are the chief objects of attack, that it is in fact a children's disease there, is another proof of the general doctrine of acquired immunity, for in nearly all endemic infectious diseases the virus attacks by preference the young because immunity protects adults.

The subject is, however, still more complicated. It would be folly to transfer the doctrine of immunity from natives of Africa to natives of our northern climate settling there. The former do not acquire all their immunity in a single lifetime. They start at birth with enough inherited accumulation of immunity to need but a little further training to come out victorious. That the Anglo-Saxon baby could do likewise is hardly within the range of probability.

The difference between the native of the tropics and the native of the temperate zone is probably dependent on a variety of physiological factors. Among these I am inclined to place differences in the biology of the red corpuscles at the front. The red corpuscle is subject to much greater vicissitudes as regards osmotic changes in the tropics than in temperate zones. With us, temperatures below a certain mean are equalized by clothing and artificial heat. Temperatures above a certain mean are not equalizable. They must be endured. Hence the heat-regulating mechanism must come into more active play, the output and intake of water is large, and with it the changes in the concentration of the salts of the blood must vary more or less. The native of hot climates is adapted to these changes, primarily by a greater resisting vigor of the red cells. The temporary resident of the tropics suffers from those disorders incidental to the taking care of corpuscular débris, foremost among which are those of the liver. Added to this natural increase in the resisting power of the red cells is one due to increased use, such as takes place when new corpuscles must replace those destroyed by use and by malaria parasites. The blood-forming organs up to a certain point are strengthened by use.

Secondly, a specific immunity due to the malaria parasite itself must accumulate through generations in infected localities, which immunity may reside both in the blood and in the host cells themselves. This subject of the relation of the red cells to immunity I can only touch upon here. It is one which I think will repay thorough investigation.

In the malaria of our latitude the effect of the parasite upon natives and those coming from still colder climates is not seen in its frankest manifestations, because quinine enters at once to suppress the disease. When treatment is neglected cases do occur now and then which indicate that malaria freshly introduced into a locality may prove serious and even fatal at times.*

In our climate the French Canadians appear to be most susceptible, and in general it seems to be true, as with yellow fever, that the further north the home of the one who immigrates into an endemic region the more severe the disease when it does appear.

A similar relation between latitude and susceptibility seems to exist in bovine malaria. The disease imported into the northern states from the southern enzoötic territory, though carried by healthy animals in their blood, is very murderous to the northern animals. On the other hand, cattle living in the tropics, but not in infected localities, are much more resistant, as indicated by Koch's experiments in Africa. The same seems to be true of the Venezuelan form of this disease, called Lomadera, and studied by Ziemann.[23] All that can be claimed from various observations upon immunity is that the influence of the malaria parasite upon the host is in the direction of a biological immunity. The latter may or may not reach a clinical immunity, for that would depend upon the degree of resistance with which the individual started in life, and the interruption of the process by the continued use of quinine.

During the immunization which goes on in the course of the manifest or latent infection, how early do the fully matured gametes appear, and how long

* "It must be understood that in speaking of a case of malaria in children we are referring only to the presence of parasites; the children are perfectly well and present none of the characteristic signs observed in Europeans affected with malaria." (Lagos, West Coast of Africa.) See Rep. to Malar. Committee. Third Series.

* In one town a young woman who was being treated without quinine told me that she had had thirty-six chills in thirty-nine days. An examination of the blood certainly confirmed her statement, for the disease had produced marked anæmia and characteristic changes in the red cells.

do they remain in the blood? After fresh infection does the highly immune body destroy the injected sporozoites or do they form gametes? These questions are proposed in view of their bearing upon the infectiousness of the individual in different stages of the disease. Schaudinn, who states that with suitable methods gametes of tertian fever may be readily detected in the blood and distinguished from the schizonts or sporulating forms, has seen the former appear in one case after the third attack. But Schaudinn made his studies in a permanently infected region on the eastern coast of the Adriatic in Istria. Thayer and Hewetson have given summaries of their observations of the sexual forms of parasites, and from their report I take the following figures: in 153 cases of tertian fever, flagellate bodies were seen in 6. Of 105 cases of estivo-autumnal fever they were seen in 18. "In a half of the cases the paroxysms had ceased; in 8 out of 20 instances quinine had been previously given; that is, for days and sometimes for weeks after the activity of the infection had certainly been overcome, we were able to see flagellate bodies. . . ."

In the case of the crescents, the gametes of estivo-autumnal fever, they found in over 70% of the cases the crescents appearing in the second week or thereafter, practically none in the first week, if two doubtful cases are thrown out (p. 173). It seems that the gametes tend to appear after the more active process has subsided, and if the conditions where these cases were studied are similar to those in our latitude we may assume that patients may be infectious in the presence of Anopheles during and after the second week. However, I am not inclined to accept fully the findings of the latitude of Baltimore or Istria for Massachusetts.

G. Maurer,[24] studying tropical malaria in Sumatra, states that gametes appear in the blood only some time after the beginning of the fever, in some earlier than in others. In some they do not appear at all. The appearance of crescents is completely suppressed when the earliest fevers are treated rationally with quinine.

There are a number of factors working against the ripening of gametes in the blood in natives of our climate. These are the absence of any inherited or acquired immunity to begin with and the prompt use of quinine. Cases may, however, remain untreated. They may possess more or less natural resistance. Even cases treated successfully in one season may have relapses in the early spring of the following season. Such cases are probably much more likely to prove sources of infection than fresh cases. In them immunity has made some progress. These relapsing cases are probably the starting-point of the infection during the year.

The most dangerous individuals are those who have lived in permanently infected localities for a long time and who possess considerable resistance. In them the virus is latent and prepared to appear clinically under satisfactory provocation. Caccini[25] made an exhaustive study of the latent virus of malaria in Italy and the causes of its occasional outbreak into a paroxysm. He found that the general condition of the people was of considerable moment. The well-fed and well-housed masters had few attacks as compared with the laborers under them. Heavy work during the vintage and harvest, gastro-intestinal troubles, a sudden chill, sleeping out of doors, being caught in rains, all predisposed to relapses. Certain foods causing vomiting, certain medicines, intercurrent illness, even sea-bathing, brought on an attack in some persons. It is related by A. Plehn,[26] with citation of cases, that persons having had no clinical disturbance in the tropics during a temporary residence because of prophylactic quinine treatment, on their return to Europe passed through a regular attack either on shipboard or in their native country. In such instances the infection occurred unperceived and may have been repressed by quinine from the start.

Though the conception of the latency of malaria is a very old one, yet its epidemiological significance has had no recognition until lately. The persistence of malaria has been chiefly of clinical interest, and the patient was considered, rather than his environment. To-day we are slowly becoming accustomed to the thought that the latter must also be considered. Absence of illness does not necessarily exclude the presence of infecting organisms, and carriers of infection must be kept in view as possible centers of disease. We are now fully acquainted with the possibility that bacteria may persist in the body after recovery. The vexatious question of diphtheria bacilli in recovered cases is present without doubt in the minds of most physicians. In typhoid fever the urine and feces may contain the bacilli after recovery. I might give many additional illustrations. But there is another fact of similar significance, namely, the presence of pathogenic bacteria in the well who have come in contact with infection. Thus, typhoid and cholera microbes have been found in the feces and diphtheria bacilli in the throat of well persons not previously diseased. This tendency toward a symbiosis between host and parasite is much more pronounced in the case of animal parasites, especially those belonging to the malaria group. Thus in bovine malaria the parasite has been demonstrated by inoculation to exist in the blood of immune animals three years after the last opportunity for infection.[27] More recently Wasielewski[28] has shown that one of the malaria parasites of birds (*Proteosoma*) remained in the blood five months after infection. The more favored theory would undoubtedly be that when the host becomes completely immune the blood parasites can no longer subsist in him, but I am inclined to believe that such complete immunity does not exist and that whenever an immune human being is infected the parasites go through the process of forming gametes or sexual elements without clinical manifestation and then await the opportunity of being withdrawn by some mosquito. Or else they await the equally desirable moment when the host has committed some indiscretion by which his resistance is reduced, when the parasite rapidly undergoes the usual asexual multiplication in the blood and calls forth a paroxysm. When equilibrium is re-established the sexual elements appear in large numbers. The forms in which the malaria organisms remain latent is a subject of great biological interest. Grassi assumed that sexual elements or gametes undergo parthenogenesis. Schaudinn recently claims to have established the

fact that the gametes may revert in part to forms which multiply asexually in the way familiar to us whenever a relapse is impending.

SUBPARIETAL INJURIES OF THE KIDNEY.

BY FRANCIS S. WATSON, M.D., BOSTON.

(Concluded from No. 2, page 35.)

THE AUTHOR'S SIX CASES.

(1) Laceration of the right kidney, and cerebral concussion. Hematuria of four days' duration. Small tumor in the loin. Expectant treatment. Recovery.

(2) Hematonephrosis — in a previously hydronephrotic kidney — and perirenal hemorrhage, without laceration of the kidney, resulting from violence inflicted upon the right side of the front of the abdomen. Lumbar nephrotomy and secondary lumbar nephrectomy. Recovery.

(3) Laceration of the left kidney. Peritoneum, renal vein and spleen. Retention of urine due to clots in the bladder. Abdominal nephrectomy twenty-four hours after the accident. Death four days later from peritonitis. Injury to spleen not severe.

(4) Rupture of left kidney and spleen, fracture of brim of pelvis, three ribs and arm on the left side. Primary abdominal nephrectomy. Spleen tamponned. Laceration of spleen severe. Peritoneum overlying the kidney ruptured. Death from shock and hemorrhage from spleen, twenty-four hours later.

(5) Rupture of left kidney. Subcapsular and intrarenal hemorrhage. Lumbar incision and suture of the kidney wound on the third day. Recovery.

(6) Laceration of the right kidney, *due to muscular effort*. Resulting hydro-, later pyonephrosis. Infection fourth week after the receipt of the injury. Lumbar nephrectomy five weeks after the accident. Recovery.

(1) *Expectant treatment. Recovery. Laceration of the right kidney and cerebral concussion.*

Hematuria noted with the first urination after the accident — a fall of twelve feet — the blood was abundant for first twenty-four hours, it was present for three days, but in less quantity after the first day. Ecchymosis in the right loin. Patient unconscious for some hours. Swelling in the right lumbar region developed slowly twelve hours after the injury. It was of moderate size and had disappeared at end of ten days. Pain was not noted on account of unconsciousness during the first part of the time following the injury. Expectant treatment. Recovery.

(2) *Lumbar nephrotomy. Secondary lumbar nephrectomy. Recovery.*

A young man was jumped on by an opponent in a street fight, the right side of the abdomen being struck by his knees, while lying on the back. This man had sustained six severe injuries to the right kidney during the previous twelve years; each time there had been hematuria, severe pain in the right loin, and each time the patient had recovered under expectant treatment.

On the last occasion operation was determined by signs of progressive and serious hemorrhage, in the form of hematuria, four days after the receipt of the injury, and by the presence of a rapidly increasing tumor which appeared on the evening of the third day. Hematuria ceased at the same time.

Lumbar incision. Kidney enormously distended by blood clot. No wound of the kidney. A considerable perirenal hematoma, the latter originating from the injured perirenal blood vessels.

Nephrotomy. The kidney was emptied of its blood clot, tamponned and drained through the lumbar incision. It had evidently been hydronephrotic for a long time. The patient made an uninterrupted recovery, but a fistula remained and the kidney was removed some months later by my colleague, Dr. Thorndike, the patient recovering readily from that operation also.

(3) *Abdominal nephrectomy (primary). Spleen, peritoneum and renal vein torn.*

A man fell fourteen feet, striking left side against a plank. Violent lumbar pain. Hematuria lasting until the operation, and blood appearing with the first urination after the accident. Shock severe, free fluid in moderate quantity, and not rapidly accumulating, in the peritoneal cavity. A tumor in the left loin developed immediately after coming to the hospital, half an hour after the injury.

Operation twenty-four hours after the accident. Abdominal nephrectomy. Incision in the left linea semilunaris. Small wound of [illegible] spleen.

Peritoneum over left kidney torn. Immense retroperitoneal hematoma, intra-peritoneal hemorrhage chiefly through the torn peritoneum from the kidney, a small part from the wounded spleen. Wound in peritoneum enlarged. Renal vein found to have been injured also. Ligature of vessels and ureter in one mass. Wound of spleen tamponned. Abdominal wound closed. Drainage through a lumbar incision. Death on the fourth day from peritonitis. Condition of kidney shown in Fig. 1.

FIG. 1. — Case 3 (author's).

(4) *Laparotomy. Tamponning of wounded spleen. Kidney not touched. Left kidney lacerated. Spleen severely injured. Fracture of pelvis, three lower ribs on left side and left arm. Peritoneum torn. Death.*

Patient, a man, fell twenty-five feet into hold of vessel, striking left side. Shock severe, hematuria with first urine, which was drawn with a catheter. The bladder was filled with clots, great pain over left kidney. A rapidly increasing and very large quantity of fluid in the peritoneal cavity. Signs of serious progressive hemorrhage. Operation four hours after the accident. Laparotomy in the left linea semilunaris, incision prolonged outward from its upper end to the quadratus lumborum. The abdominal cavity filled with blood, principal source of which was the lacerated spleen, a smaller part of it coming from the kidney through rent in the peritoneum. Patient's condition too critical to allow of more than tamponning the spleen wounds, and draining through the loin. The patient died fourteen hours later from shock and continued hemorrhage, from both spleen and kidney. Fig. 2 shows the condition of the kidney, as seen postmortem.

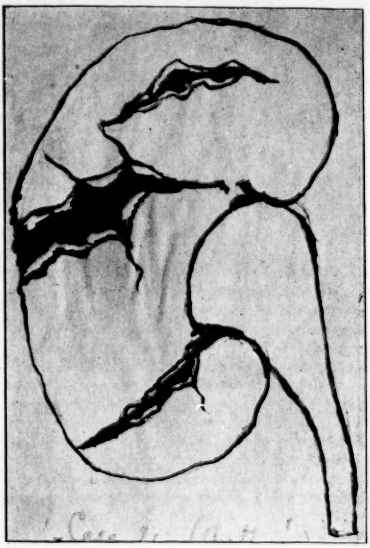

FIG. 2. — Case 4 (author's).

(5) *Lumbar incision and suture of the kidney wound. Left kidney ruptured. Subcapsular hemorrhage. Obstruction of ureter on the fourth day by clot. Recovery. Fistula persisted. Second operation. Pseudohydronephrosis. Recovery. Later condition not known.*

A man fell while stepping off his cart, striking the left side of the back. Great pain in the seat of injury. Hematuria profuse with the first urination. This continued, though in somewhat less degree, for the next four days, the patient's general condition being good during the interval. On the night of the fourth day sudden cessation of hematuria, development for first time of a tumor in loin, this grew rapidly. Operation one hour after the appearance of these symptoms.

Kidney exposed in the loin by lumbar incision. There was a very moderate amount of blood around the kidney. The organ itself was enlarged to more than twice its normal size, and the pelvis was enormously distended by blood clot. The kidney was of a dark purple color.

The fibrous capsule was not torn. There was a laceration of the kidney which is shown in Fig. 3. From it protruded beneath the fibrous capsule a blood clot, which had dissected the capsule from the kidney over nearly the whole of the posterior surface of the organ.

The capsule was incised and the clot expressed through the wound in the kidney by pressure with the hand upon the distended pelvis. The vessels, ureter and pelvis were not injured. The kidney at once resumed its normal size and color on being freed from the clot. No urine was found in the pelvis. The wound in the kidney was closed by seven catgut sutures. Hemostasis was complete

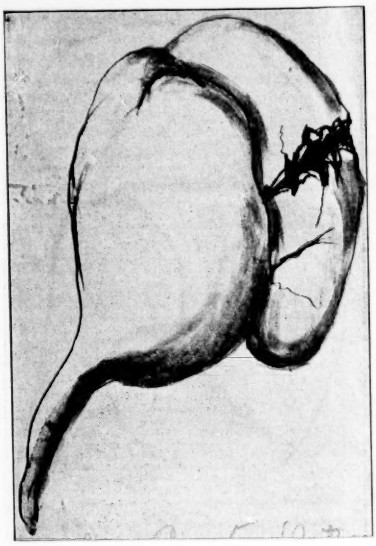

FIG. 3. — Case 5 (author's). Pelvis distended with blood clot.

and immediate, and the wounded surfaces adapted themselves perfectly. (See Fig. 4.)

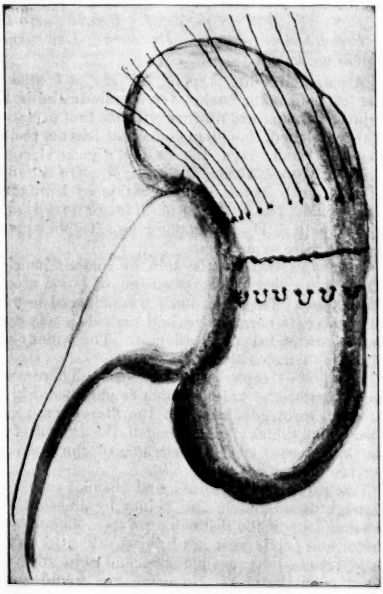

FIG. 4. — Case 5 (author's). Showing closure of wound by suture after removal of blood clot.

The patient made an uninterrupted recovery, but a fistula established itself after the wound had been closed without leaking for five or six days, and the patient had gone home. He presented himself again about two months later to have the fistula closed. The condition of the kidney found at the second operation was that usually termed pseudohydronephrosis, and is shown in Fig. 5.

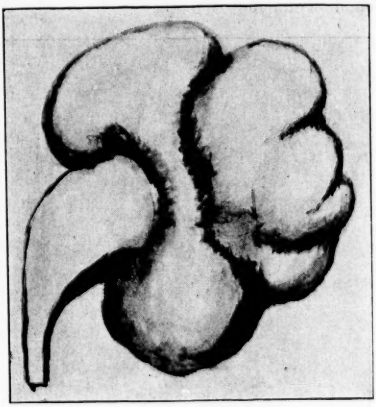

FIG. 5. — Case 5 (author's). Condition found at second operation.

The kidney was exposed in the loin through the old incision. Its anterior surface was adherent to the overlying peritoneum. The fistulous tract led to a sac about the size of a large hen's egg on the outer and posterior surface of the kidney. This sac was incised. No communication could be established between its interior and that of the kidney. Its inner aspect was apparently represented by the kidney's outer surface, and the remainder of its walls by more or less organized exudate. The walls were excised in part, and drainage supplied through the lumbar incision which was otherwise closed.

The patient made a rapid recovery from this operation also, but when discharged from the hospital the fistula had not closed, and was still open when he was last heard from, one month later, two months from the time of the second operation.

(6) *Lumbar nephrectomy for pyonephrosis*, resulting from a laceration of the right kidney five weeks previous, which injury was caused by the slight muscular effort made in stretching up quickly to reach the top of a window which the patient was washing.

The patient was a large woman. Five weeks before the operation she was washing a window, and on making a sudden effort to reach the top of it felt a violent pain in the right kidney, became faint, and vomited. Hematuria of moderate degree was seen at the second passage of urine after the accident, and the urine was noted as being rather red for the next two days. The pain lessened and vomiting ceased after a few hours, and faintness passed off. After a few days she was up and

about again, but did not resume her work again on account of a sense of discomfort and tenderness in the right renal region. Three weeks later this became more marked, and at the end of that week she was seen by Dr. Kelly, who then felt a tumor of moderate size, corresponding to the right kidney in contour and position. He sent her to the hospital, where she remained under observation for a week longer and was then transferred to the surgical service. The tumor during this — the fourth — week had increased in size, and now extended from the free border of the ribs to below the margin of the pelvis, filling the right side of the loin and part of the abdomen. It was tender to touch. On the day of her admission to the hospital the temperature rose to 101°F, and pus appeared for the first time in the urine. Operation, June 2, 1903.

The kidney was exposed in the loin, and found to be greatly distended by pus, and saculated. The contents evacuated through a trocar, and the interior of the organ irrigated. The kidney was firmly adherent to the overlying peritoneum and the under surface of diaphragm, and less so to the lumbar fascia. The adhesions were separated from the fibrous capsule except in front, where the capsule was peeled off and left attached to the peritoneum.

The *ureter* was adherent, for the first four inches of its length, to the lower pole of the kidney, was greatly thickened, and, although not occluded permanently, had probably been closed at intervals at the point corresponding to its adhesion to the lower end of the kidney.

The pedicle, which was very short, was tied in two parts, the vessels in one, the ureter in the other.

The outer wound was partly closed, leaving free space for drainage by iodoform wicks.

The appearance of the kidney is shown in Fig 6.

There was a partially healed laceration extending transversely across the outer convex border, to midway on both the front and back surfaces of the kidney. At each end of this wound was an opening large enough to admit the tip of the little finger.

The part of the wound on the anterior surface was more firmly closed than that of the posterior, but both were sufficientiy tight to have prevented any escape of the kidney contents into the perirenal tissue. The appearance of the kidney suggested that the organ had been hydronephrotic previous to the accident. There was, however, upon microscopic examination no disease other than hydronephrosis found to exist. The patient made a slow but good recovery.

TREATMENT.

The most noticeable features in the analysis of all the clinical data are the *high* death-rate attending the expectant treatment, as compared with any form of operative intervention, and the conspicuously *low* mortality of the series of cases treated by operations other than nephrectomy.

The expectant treatment shows at its worst in the cases with intra-peritoneal complications. It cannot, of course, be positively asserted that some of these having abdominal symptoms, treated expectantly and recovering, may not have had an intra-peritoneal injury, but the presumption in that case is, that if it did exist at all, it must have been of moderate character, and we are probably warranted in saying that no patient who has had such complicating injury of a serious nature has recovered under expectant treatment.

The low mortality in the series treated by operations other than nephrectomy, compared with that attending the latter, is obviously due to the fact that the operation which was selected instead of nephrectomy — lumbar incision and suture, tamponning and drainage, or nephrotomy, etc.— was chosen for the reason that the kidney was not found to be so seriously damaged as to require nephrectomy. In other words, the cases were of a less grave nature.

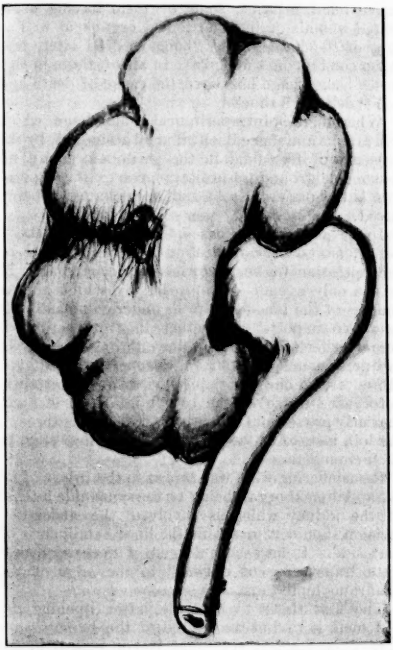

FIG. 6.—Case 6 (author's). Pyonephrosis following subparietal laceration of the kidney produced by muscular effort.

The reason for the even greater difference in the death-rate of this class as compared with that of those treated expectantly is equally clear. It is furnished by the fact that the operations other than nephrectomy save almost all such patients as those who die from hemorrhage or suppuration under expectant treatment.

Thus, these operations which were done for one or the other of the two conditions — suppuration or hemorrhage — in 85 out of 99 uncomplicated cases were attended by five deaths only, whereas 66 died from the same causes out of 81 fatal cases, in the total 273 treated expectantly, 5% of the whole number of cases in the former, as contrasted with 24% in the latter.

Hemorrhage is the one factor which most frequently demands *prompt* operative treatment.

Ordinary surgical common sense leaves no room for doubt as to the necessity for operative intervention in the presence of the signs of *progressive* hemorrhage. The only question that can arise is from the difficulty, soon after the accident, of discriminating between shock and hemorrhage. The characteristic feature ordinarily of the former is that it is at its height immediately or soon after the receipt of the injury, while that of the latter, if the bleeding continues, is the increasing seriousness of the symptoms.

There have been a few patients who showed remarkable absence of shock after receiving very grave renal injuries, some of them having associated wounds of intraperitoneal organs as well as that of the kidney, and who have died later, collapse coming on suddenly. In all of these in this series hemorrhage has been the cause of death and not "delayed" shock.

When there is intraperitoneal hemorrhage, which will always announce itself, if at all abundant, by the presence of free fluid in the peritoneal cavity, no reasonable ground for hesitation can exist. Operation is the patient's sole and only chance of being saved.

In the latter class of cases, there is, in the author's belief, moreover, no question as to the nature of the operation to be performed. *Laparotomy* will be the only avenue of approach by which all the sources of the bleeding can be under command. It is of no importance whether the intraperitoneal hemorrhage is from the kidney through a rent in the peritoneum or from an intraperitoneal organ. Moreover, no one can determine with any certainty beforehand which of the two it is. Loss of time, that may prove fatal, may result from going through the loin instead of the abdomen as the first step, in such circumstances.

Remembering what was said as to the injury of an intraperitoneal organ being on the same side as that of the kidney which is involved, the abdominal incision should be made in the linea semilunaris of that side. It may be enlarged, if necessary, best by a transverse cut outward to the edge of the quadratus lumborum.

The first thing to be done, after opening the abdomen, is to find the source of the hemorrhage.

If it is the left side that is concerned, in all probability the spleen is furnishing the greater part of the blood.

Do not stop at this time to clean the abdomen of blood, but *feel* for a wound in the spleen.

If none is found, the kidney is the next most likely source of the bleeding. The peritoneum overlying it should therefore be examined. If hemorrhage is found to be proceeding through a rent in the peritoneum, enlarge it with the fingers, and seize the renal vessels. The patient may *now* be turned upon the opposite side, the abdomen cleared of blood, and the field of operation exposed to view.

According to the character and nature of the damage to the kidney, one or another of a number of operations will be done.

As a fundamental principle, save the kidney or as much of it as possible.

If the blood vessels, pelvis and ureter are intact, and the injury to the kidney is not too great, tampon, or suture, the renal wound and drain through a lumbar incision. If one end only of the organ is damaged, do a partial nephrectomy, closing the resulting wound of the kidney by suture. If the hemorrhage is intrarenal, nephrotomy should be done, tamponning the renal wound and removing the packing after twenty-four hours or so, or closing it by suture, if assured that complete hemostasis can be secured by this means. Supply drainage through the loin by a supplementary incision, and close the abdominal wound.

If the damage to the kidney is too great to allow of these measures, or if the renal blood vessels, pelvis or ureter are injured,— unless in the case of the two latter the wound is capable of being successfully sutured,— nephrectomy should be done.

Do not try to close the wound in the overlying peritoneum if the patient's condition is — as it probably will be in most cases — critical.

Make a lumbar incision for drainage in connection with the nephrectomy, as was advised with regard to the other operations.

If it is the *spleen* from which the hemorrhage is proceeding, and unless the injury to that organ is found to be of slight extent, splenectomy gives the patient his best chance, trusting to pressure by tampon to arrest whatever part of the hemorrhage proceeds from the kidney, rather than to undertake a nephrectomy in connection with the other operation. The spleen does not admit of suture or tamponning that can be relied upon. If one must choose whether the spleen or the kidney shall be removed, let it be the spleen. Splenectomy and nephrectomy were performed simultaneously in two cases only; both were fatal. Splenectomy alone, leaving the kidney undisturbed, was done successfully in two others.

If it is the right side, and the *liver* is involved, tampon or suture are appropriate, and have been successfully applied, either in connection with nephrectomy or other operations upon the kidney, performed at the same time or not, according to circumstances.

In the rarer cases in which other structures than the spleen or liver are associated with the injury to the kidney, the general principles which are applicable to such conditions ordinarily should be carried out. The intestine, for example, will be resected, or sutured bleeding vessels of the mesentery or omentum ligatured, etc., according to circumstances.

UNCOMPLICATED CASES.

It is more difficult sometimes to decide what is best to be done in uncomplicated cases. Such, for instance, as do *not* present evidence of progressive hemorrhage, or that suppuration has occurred, but in which either one or the other may be looked for.

How long is it safe to allow hematuria to continue? How long may a tumor in the loin be left to itself if it has not begun to subside? What are the chances of infection, and how can we know in which cases it is likely to occur or the reverse?

The study that we have made supplies answers in some measure to these questions.

With regard to hematuria. In spite of the fact that, *per se*, it rarely causes death, this in itself cannot be relied upon as a guide to treatment.

This much, however, may be asserted with some confidence, namely, that the great majority of cases in which hematuria is either of short duration even though very profuse — not more than thirty-six hours — or of much longer duration, if the quantity of blood is slight, when it is not secondary, and finally, when there are no signs of progressive hemorrhage shown by the patient, may — so far as any danger from hematuria alone is concerned — be treated expectantly. When the contrary of the above conditions exists, operative treatment should not be delayed.

The conditions presented by the 8 cases dying from hematuria were as follows: It was reported as being secondary in 7. In 3 *death* occurred under expectant treatment, and in 4 after operation. There were 16 cases of secondary hematuria altogether, 5 of which *recovered* under expectant and 4 under operative treatment. The remaining fatal case of the 8 died of exhaustion produced by three weeks' continuous hematuria, in which the amount of blood, though considerable, was not excessive at any one time.

Conditions in connection with hematuria which call for prompt surgical treatment are: (1) The sudden disappearance of blood from the urine, if accompanied by pain, and the appearance, or if already present an increase in size, of a tumor in the loin. These show that the pelvis or ureter has become blocked by blood clot or debris, and demand prompt surgical treatment. (2) Retention of urine due to the presence of blood clots in the bladder. (3) Profuse hematuria continuing longer than thirty-six hours. (4) Prolonged hematuria, unless the blood be in small quantity, and (5) secondary hematuria. (6) Signs of progressive hemorrhage, which under all conditions calls for surgical intervention.

In perirenal hemorrhage surgical intervention is called for by the following indications: Rapid increase in the size of the tumor, or gradual increase if it be prolonged.

The nature of the operation will be determined in the same manner as was described when speaking with regard to this point in connection with the conditions of the kidney found when performing the abdominal operation in cases complicated by intraperitoneal injuries.

It is as clear, in the writer's opinion, that all *uncomplicated* cases should be approached by the lumbar incision primarily, as it is that laparotomy should be the first step in those having intraperitoneal complications.

The question whether one should interfere surgically in *anticipation* of the actual occurrence of infection, and in order to avert it, is one of the most interesting aspects of the subject so far as treatment is concerned, and is certainly open to discussion.

On the one hand we have the fact that of the uncomplicated cases, in which the patients escape the dangers of primary hemorrhage, — which class alone is meant to be considered in this connection, — far the larger part recover without infection having occurred under expectant treatment. On the other we know that suppuration does take place in a considerable number, and when it does it is a serious matter. Also there is no way of determining beforehand whether it will occur at all, or at what time it is likely to do so. Furthermore we know that every lacerated kidney is liable to infection, and that the longer perirenal extravasation or hydronephrosis exist, the greater is the liability to it.

Surgical intervention seems to the writer to be indicated, for the purpose of guarding against, and in anticipation of, the actual occurrence of infection in the following circumstances:

(1) When there is a tumor in the loin — whether it be perirenal extravasation, hydronephrosis, or hematonephrosis — which does not begin to subside within a reasonable time, let us say a fortnight at most.

(2) When the bladder becomes or already is infected, or is especially liable to be so because of the necessity of frequent catheterization, as, for example, with patients having prostatic hypertrophy, or when there is retention due to blood clots.

(3) When there is reason to suspect the previous existence of such diseases of the kidney as tumors, calculus, pyelitis or pyelonephritis.

In the absence of the above conditions, it seems wiser to take the chances of infection, and treat the patient expectantly so long as it does not occur, reserving surgical procedures until it announces itself, and then operating promptly.

SUTURE OF THE RENAL WOUND.

The writer has been able to find but seven cases of subparietal injury in the literature of the subject, in which suture of the renal wound has been done for laceration of the kidney, with his own included eight altogether. These are as follows: Tuffier, in 2 cases; Peyrant, 1 case; Bidault, 1 case; Phillipe-Liege, 1 case; Delbet, 1 case; Brewer, 1 case; Watson, 1 case. In six of the above cases the procedure was most successful, the wounds uniting quickly, and convalescence being materially shortened.

The two cases in which suture was not successful were those of Delbet and of the author. In the former the patient made a good operative recovery, but secondary nephrectomy some time later resulted fatally. In the author's case, fistula, as described in the report of Case 5, resulted.

One notable feature is mentioned by all of the above-named surgeons; namely, that suture of the lacerated wound produced immediate and entire hemostasis.

In view of these facts, and the well-known readiness with which wounds of the kidney — traumatic, if not too extensive, as well as incised — heal, it would seem worth while to apply suture in such conditions as warrant it in these cases of subparietal injury, as well as in exploratory renal incisions, for the closure of which it is frequently employed. Some writers have entirely condemned it, but most of them in referring to it preface their remarks by saying that they have never used it personally, having found tampon and drainage entirely satisfactory to them.

A COMPARISON BETWEEN LUMBAR AND ABDOMINAL NEPHRECTOMY.

Lumbar nephrectomy in subparietal injuries has

been credited by most writers with a much smaller mortality than the abdominal operation. In no previous publication of this class of cases has there been a sufficient number of nephrectomies to warrant this conclusion. The inference has rested moreover in some instances upon the face value of the cases treated by the two methods respectively, without regard to their character; that is to say, the comparison has been made between the total number of each, including both the uncomplicated and complicated cases as well. Inasmuch as there are more of the latter in which abdominal nephrectomy has been the operation done, than of those in which the lumbar method was employed, this is manifestly unjust to the former operation.

Although the number of nephrectomies in the series collected by the writer is nearly four times as many as that of Delbet, — 160 in the former, 44 in the latter,—it also is entirely inadequate for the purpose of drawing final conclusions. It does serve however to show the fallacy so frequently indulged by medical authors; namely, that of relying upon too small a number of data for their conclusions, since even upon the face value of the figures in this much larger number of cases, the verdict in favor of the lumbar operation is contradicted in a large measure; there being a difference of but 4½% in the death-rate in favor of the lumbar operation as compared with the abdominal, that of the former being 27% and of the latter 31% plus.

If, however, the complicated cases are separated from the uncomplicated in both the lumbar and abdominal operations, and compared respectively, the following facts appear:

There are but 11 complicated cases out of the 81 lumbar operations, and 7, or 63% of them, died, whereas there were 33 complicated cases out of the total number of 44 abdominal operations, and of these but 12, or 36%, died.

In other words, there were three times as many complicated cases treated by the abdominal operation as by the lumbar, and only about half as large a percentage of the former died as did of the latter.

The showing of the results of nephrectomies for *various renal conditions*, presented in Schmieden's article for a much larger number of cases, is very instructive in certain respects, as well as very hopeful, the latter because of the remarkable decline in the death-rate attending both the lumbar and abdominal methods during the last thirty years, as demonstrated by a comparison of them in three successive periods of ten years each, 1870–1900, inclusive. This is as follows:

The total number of nephrectomies was 1,118, collected from various sources.

This number is classified as follows:

Total number of cases, 1,118; deaths, 301; mortality, 26.9%.

	Recoveries.		*Deaths.*	
1st ten years,	40	or 49.4%.	41	or 50.6%
2d " "	319	" 66%.	164	" 34.0%
3d " "	458	" 82.6%	96	" 17.4%

LUMBAR OPERATIONS.

	Recoveries.	*Deaths.*	
1st ten years,	23	18, or mort. p. c. of	43.9%
2d " "	231	85, " "	26.9%
3d " "	303	62, " "	17.0%
Total number	722. 557	165	22.9%

ABDOMINAL OPERATIONS.

	Recoveries.	*Deaths.*	
1st ten years,	18	22, or mort. p. c.	55.0%
2d " "	83	77, " "	48.1%
3d " "	133	32, " "	19.4%
Total number	365. 234	131	35.6%

The above figures show the following details: First, the remarkable diminution of the death-rate for both methods, during the thirty years,—in the lumbar operation of 26.9 %, and in the abdominal of 35.6%. Next, the steady gain in the successive periods in the recovery percentage of the abdominal operation, as compared with the lumbar, the difference in favor of the latter in the first ten years being 11.1% and in the last ten years but 2.4%.

ADDENDA.

It is impossible to give a full bibliographical list of the somewhat more than 600 writers whose works or reports of cases have been studied in detail by the author while preparing this paper, but in order to save labor for those who may wish to consult the literature of the subject a list of the more important *series* of cases and writings published up to the present time is herewith appended alphabetically. In this list are included all but 103 cases of the total 660 comprising the whole series collected by the author, these 103 being made up of the 25 hitherto unpublished cases, and 78 individually reported ones found by the author in the literature.

Albarran.
Bloch, 1873. 40 cases.
Cerou. 8 cases of anuria. Thesis. (Quoted by Morris.)
Davis, 1902. 23 cases. (Annals of Surgery, Philadelphia, vol. xxxvi, No. 3, p. 346.)
Dodge, 1902. 9 cases. (Annals of Surgery, Philadelphia, vol. xxxvi, p. 897–920.)
Delbet, 1901. 320 cases. (Ann. des Mal. des Org. genit.-urin., vol. xix, p. 669–805.)
Dolgoff, 1900. (N. Y. Med. Journ., lxxii, p. 871.) Experiments.
Edler, 1887. 152 cases.
Goldstein, 1902. 20 cases. (Deutsch. Zeitschr. f. Chir., Leipzig, vol. lxv, p. 87–98.)
Guterbrock. 1895. 35 cases. (Autopsies, with relation to frequency. See Morris.)
Hohlbeck, 1898. 14 cases. (St Peters. Med. Woch., N. F., xv, p. 449–452.)
Grawitz, 1888. (Arch. f. klin. Chir., Bd. xxxviii, p. 436.)
Johnson, 1898. 7 cases. (Annals of Surgery, Philadelphia, vol. xxxvii, p. 774.)
Keen, 1896. 118 cases. (Annals of Surgery, Philadelphia, vol. xxiv, p. 138–181.)
Küster, 1896. 306 cases. (Deutsche Chir. Lieferung, 52b, S. 196, 1896.) 1895. (The mechanism of the injury. Arch. f. klin. Chir., Berlin, vol. l, p. 676–686.)
Maas, 1878. 71 cases. (Deut. Zeit. f. Chir., Bd. x, p. 126.)
Morris, 1901. (Surgical diseases of the kidney and ureter.)
Obalinski, 1891. (Samml. klin. Vortragé, [Volkmann's], Leipzig, N. F. 16.)
Petroff, 1901. (Thesis, Lyons, A. Storck & Co., Publishers. On intraperitoneal ruptures of the kidney.)
Quervain, 1901–1902. On intraperitoneal ruptures. (Deutsche Zeitschr. f. Chir., vol. 62, p. 58.)
Schmieden, 1901–1902. 36 cases. (Deutsche Zeitschr. f. Chir., vol. 62, p. 205.)
St. Thomas Hosp. Rep. 27 cases.
Tuffier, 1899. 198 cases. (Duplay et Reclus, Surgery.)
Wagner, 1900. 27 cases. (Schmidt's Jahrb., Leipzig, vol. cclxvi, p. 90.)
Waldvogel, 1902. 20 cases. (Deutsche Zeitschr. f. Chir., Leipzig, lxiv, p. 39.)
Wallis, F. C., 1897. 14 cases. (Trans. Clin. Soc., London, vol. xxx, p. 38.)
Wyss, 1901–1902. 14 cases. (Beitr. z. klin. Chir., Tubingen. xxxii, p. 242.)

Delbet's article in 1901 contains a summary of 320 cases; includes all of those published by Keen, Maas, Grawitz, Bloch, Obalinski, Wallis; also, almost all those of Küster and Tuffier, and of the series of Wagner's previous to that included in this article the theses of Foy, Moser, Ravel, Martin, Poireault, Gargam, Sladowski, Pean, Pfeiffer and Bidault.

In my own compilation I have included such cases prior to 1901 as were not included by Delbet in his series, and all that were accessible to me published between Delbet's article, 1901, to the present time, June, 1903, to the number of 340, which, added to those of Delbet, makes a total of 660, comprising the whole series.

Clinical Department.

CLINICAL MEETING OF THE STAFF OF THE MASSACHUSETTS GENERAL HOSPITAL, FEB. 20, 1903.

INSULAR SCLEROSIS; CHARCOT JOINTS.

DR. J. J. PUTNAM showed patients illustrating these conditions. The two patients whom I am about to demonstrate, illustrate some of the difficulties in the diagnosis of insular sclerosis. This is a matter which has been attracting a good deal of attention of late years and about which neurologists have by no means come to a definite conclusion. A paper published recently by a German observer gives it as the author's opinion that there are more than twenty different diseases with which this one might be more or less easily confounded.

This difficulty is due, of course, in great measure to the fact that the arrangement of the areas of disease seems to be entirely independent of any special distribution of nerve tracts in the central nervous system, and also independent of vascular areas; furthermore, the nerve elements themselves within the limits of the morbid change are damaged but not destroyed, and on this account we are liable to get clinical pictures which suggest disorders of function rather than actual loss of function of the parts disturbed.

Not only is this disease difficult of diagnosis, but the frequency of its occurrence seems to vary according to locality, although of course it may be that the latter fact is only apparent and is in reality dependent upon the former. In our clinic we have hitherto seen only a very few cases, whereas in Edinburgh vastly greater numbers are reported (by Dr. Bramwell).

At the present moment three patients are in attendance on the clinic who show the signs of the disorder in a fairly typical form, and yet even in these cases the diagnosis has to be made by putting all the evidence together rather than by the presence in a pathognomonic form of the various characteristic signs, of which the scanning speech, the intention tremor and the nystagmus are among the most striking.

The first patient to whom I call your attention has a tremor, which on the whole increases in proportion to his muscular efforts, and which is present in slight degree even when the patient is apparently at rest, as so often happens. This patient shows no scanning speech and no nystagmus, but on the other hand he has a well-marked atrophy of his left optic nerve and his enunciation is slightly drawling in character. His memory is also poor and his hearing on one side for air and bone conduction is markedly affected. Most of these symptoms date back only for two or three years, but he says that when he was a young man he and his friends used sometimes to take turns in shaving each other, but they were usually unwilling to have him act as barber because his hand used to shake.

The second patient, a young man of a little more than twenty, has a tremor which could hardly be called "intentional" by any stretch of definition. It is really a fine oscillation hardly distinguishable from that which is due to toxic conditions, or that which occurs at a constitutional neurosis. His speech is perhaps rather slow and a little dragging, but not characteristic. On the other hand, he has a well-marked nystagmus, noticeable even when the eyes are directed forward.

Finally, I will pass around some striking sections made by Dr. E. W. Taylor and Dr. G. A. Waterman, from the spinal cords of two other patients. These are interesting partly because one of these postmortems, which was done some years ago, was among the first made in this country, a fact which seems to bear out my statement that the disease is comparatively rare among us. The diagnosis in both of these cases was a matter of doubt. In one of them, although it was considered as not improbable that this disease was present, it was also believed that the case might be one of glioma of the pons. The other patient exhibited in the course of her illness a great variety of morbid signs and symptoms, quite sufficient, as I now think, to have established the diagnosis. Nevertheless, for some years before her death she was in a condition of well-marked spastic paralysis, which confined her to her bed and chair, and threw all other symptoms into the shade. This case is interesting from another point of view. It has, namely, been recognized that one of the diseases for which insular sclerosis may be mistaken is hysteria, and that diagnosis suggested itself several times to persons who examined this patient during the early part of her illness. At one period, when she was so much paralyzed and her muscles so rigid that she was ordinarily unable to walk alone, she several times walked across the floor in a somnambulistic condition, to the occurrence of which she was subject. The truth is that hysterical manifestations not infrequently are superadded to the other symptoms in this affection, apparently in consequence of the damage to the nerve elements of the brain and pons, to which I have above alluded.

The other two patients are affected with tabes, and exhibit the so-called Charcot's joint in its most typical form. (Radiographs illustrating the conditions present were here shown.) In one case it is the knee that is affected, in the other the hip. In the latter it is evident from the physical examination that either the head of the femur is entirely out of joint or else that it is lacking altogether. In fact, the radiograph shows the latter to be the case.

DR. ARTHUR K. STONE first showed

TWO CASES OF ANEURISM.

CASE I. *Aneurism of the aorta* — (by permission of Dr. Fitz).

The patient is a Scotchman, age sixty-two, and a carpet-layer by occupation. He denies all venereal history, and there is nothing in his past history which bears upon the present condition. Hoarseness was noticed first about a year ago. This came on suddenly and later let up for a time, only to return again. For the past three months there has been marked hoarseness and persistent coughing, rasping in character. A few weeks ago there was some pain on swallowing.

Patient is very thin; chest appeared generally resonant on percussion, and auscultation showed diffuse dry râles, and heart area and sounds practically normal. Examination of the larynx by Dr. Cobb showed a paralysis of the left vocal cord. Re-examination in the light of this finding showed the apex in fifth interspace, one-half inch within the nipple line or three and one-half inches from the mid-sternal line. The right border was to be made out three fourths of an inch to the right of the median line. Sounds regular and normal, excepting the second aortic, which was increased.

There was no pulsation in the neck; there was no trachial tug. The pulse at the wrists was very nearly equal. Later it was decided that the left was weaker. Blood pressure taken by Dr. R. C. Cabot showed that the presure in the left arm was slightly greater than in the right. Both chests hyper-resonant, excepting directly over the sternum at level of second rib there was a small dull area. Respiration behind high pitched, and over an area about three inches in diameter the breathing was bronchial in character. Heavy percussion over the upper portion of the hyper-resonant left chest showed some dullness above and below the second rib to the left of the sternum, but the bounds were indefinite.

The impression given by the examination even after knowing that there was paralysis of the left vocal cord was that there was probably a slight dilatation of the arch of the aorta, which had taken place just at the point where it had involved the recurrent laryngeal nerve. The fluoroscopic examination of the chest showed a round, pulsating shadow. Extending from the first rib to the fourth rib at a point an inch above the nipple, it extends three inches to the left from the mid-sternal line, an aneurism with a shadow nearly five inches in diameter.

Without the aid of the x-rays no one would have been able to have given a correct estimation of the size of the aneurism present.

(X-ray plate and the man were shown, and percussion attempted by many of the physicians present.)

CASE II. *Aneurism of the sub-clavian and embolus of the brachial artery.*

The patient was a powerful man of thirty-two years of age, a freight handler by occupation. He denied all venereal disease and excess of alcohol. He had always considered himself well till about a week before, when, during breakfast, his right hand suddenly became numb, and he found that he could not grasp as well as with his other hand. Later he noticed that his right hand and forearm were colder than the left. He was referred to the medical room from the nerve room. There was a small fusiform aneurism in the right subclavian artery, with pulsation to be seen and felt above the clavicle and outside of the insertion of the sterno-cleido-mastoid muscle; the size is, roughly, about one inch by two inches. No pulse was to be felt in the right wrist, nor anywhere in the forearm until the elbow was passed; here the beats were well marked once more. The right hand and forearm felt colder to the touch than the left, and the surface thermometer registered 83° on the right and 88° on the left. Sensation in the right hand was normal. Examination of the other organs of the body showed nothing abnormal. Evidently there had been an embolus set free from the aneurism, which had lodged in the brachial artery at its branching into the radial and ulnar arteries. The advice of the surgeons as to the desirability of operation was asked.

The two cases next presented by Dr. Stone demonstrated the well-known fact that specific disease frequently simulates new growth, and that in apparently most unfavorable conditions potassic iodide may yield unexpected results.

SPECIFIC DISEASE SIMULATING NEW GROWTH.

CASE I. *Multiple Tumors at the Elbow and on the Sternum.*

The patient was a slaughter-house workman twenty-eight years old. He had had a sore on his penis seven years before, which was not followed by any secondary manifestations.

He had been well till about one year ago, when he began to have pain and ache across his shoulders. Movements of the arms became painful. A swelling appeared at the inner side of the left elbow which increased in size and gradually became a purple red color.

Examination showed the internal organs apparently normal in condition. The patient, however, looked wretched and sick, and had a temperature of 101° F. There was a dark purple swelling over the inner condyle of the left humerus about two inches in length and an inch in breadth. The swelling was tender, there was some limitation of motion of the elbow, and apparently the swelling was attached to the bone. (No x-ray was taken, as the patient seemed so sick that he was sent at once to the house.) Over the sternum there were three slightly-raised semi-fluctuant reddish nodules of about one-half inch in diameter, and the insertion of the sterno-cleido-mastoid was thickened. All of these nodules were tender. There was also tenderness over both acromial processes, particularly the left. The general appearance of the man, and the position of the tumor, made it seem probable that the process was that of a sarcoma of the arm with secondary deposits in the sternum. The fact that there had been a chance of the introduction of syphilis seven years before, although unsupported

by any history of secondary manifestations, indicated anti-specific treatment. It chanced that the hospital was full when he applied for admission, and when the patient returned for entrance at the end of a week the improvement that he had made under specific treatment made it unnecessary that he should enter the wards. At the end of two weeks there was no trace of the tumors on the sternum, the pains had all disappeared, and he was able soon afterwards to go back to work. He is still upon potassic iodide, and the tumor over the condyle can be made out with difficulty. The skin over the tumor has returned to its normal color.

CASE II. *Enlarged nodular liver.*

The patient is an Italian, forty years of age. Little could be made out of his history except that he had "rheumatism" fifteen years ago. No venereal history was obtained and no scars found upon his penis. He has a family of seven very healthy children. He has used both alcohol and tobacco in great abundance. About six months ago there was some blood in the stools. This was probably bright blood, as I do not believe that tarry stools were meant or described. Two months ago he noticed a lump in the upper part of the abdomen, with moderate general pain. For the previous two weeks there had been blood in the stools, great general weakness, though the appetite and digestion were both good. There was and had been no jaundice. He looked sick and very dull and heavy.

Examination showed slight arteriosclerosis. The lungs were normal. The heart, though not enlarged, had a soft systolic murmur at the apex transmitted to the axilla and a slight accentuation of the second pulmonic sound. The whole upper portion of the abdomen between the arch of the ribs looked full, and was resistant and boardlike on palpation. The liver dullness extended from the sixth space on the right to 4 cm. below the costal border and continuous across to the left costal border. The edge, however, was not to be palpated. The spleen was just to be felt below the costal border. Below the zyphoid and just to the right of the median line, and apparently in the mass of the enlarged liver, were two nodules, the larger 1.5 cm. in diameter, which descended on respiration together with the mass beneath. The urine was normal and a stained specimen of blood showed only a slight leucocytosis. The appearance of the man, the enlarged and nodular liver in spite of the absence of jaundice and stomatic disturbance, made carcinoma seem the probable eventual diagnosis. Anti-specific treatment, however, made him return within a week, smiling, and feeling much better. The nodules were less easily palpated. A week later, and the nodules were not to be made out. The patient was feeling well, there was no pain and he felt able to return to work. Examination still shows a much enlarged liver, though the boardlike condition of the upper abdomen has partly disappeared. Certainly there has been a most marked amelioration of the symptoms in the few weeks' treatment. My experience has been that when new growths yield to so-called anti-specific treatment they do so within a short time and to moderate doses of the iodide.

(To be continued.)

Medical Progress.

REPORT ON DERMATOLOGY.

JOHN T. BOWEN, M.D., BOSTON.

THE RELATIONSHIP OF ERYTHEMA MULTIFORME AND LUPUS ERYTHEMATOSUS TO GENERAL TOXEMIA.

GALLOWAY and McLeod[1] report several interesting cases of this association. The first case was that of a woman of twenty-one, who entered the hospital suffering from a severe dermatitis of the face, hands and feet, accompanied by some fever. There were symmetrical red patches on the cheeks, which met across the nose and extended down to the chin. There were some red patches also behind the ears. There was considerable exudation from these areas, with crusts and desquamation. There were also erythematous areas on the backs of the hands and feet. There was some tendency to ulceration about the nails. Small erythematous lesions were also present on the forearms. On the feet and ankles the eruption was multiform, beginning with erythematous patches which tended to form vesicles or bullæ, and finally to crust or ulcerate. The gums and mucous membrane of the mouth were also affected. The urine was small in amount, of specific gravity 1.021; alkaline reaction; urea, 3 %; albumen 3 %; deposit of urates and epithelial, hyaline, and finely granular casts. The patient remained in the hospital until her death in a little less than a month, during which time she continued to have considerable fever of a remittent type. The blood was examined several times with negative results. At the autopsy it was found that the patient had evidently died from nephritis. The microscopical examination of a piece of skin excised from the right hand showed in the corium the usual signs of an acute inflammation of the skin. The epidermis showed definite changes. The Malpighian layer was edematous throughout; and in one or two places there was vesicular formation. There was also a reticulation in places. There was also a condition of parakeratosis present. The writers looked upon this as an exceptionally severe erythema multiforme, the result of toxemia produced by the disease. They had some difficulty in excluding an acute generalized lupus erythematosus.

The second case was considered without doubt an acute form of lupus erythematosus, with a close resemblance to erythema multiforme. The patient was a woman of thirty-six, who presented patches of erythema on the face, hands and arms. They were specially pronounced on the backs of the hands, and there were also lesions on the fingers. There was slight superficial atrophy of the skin in areas previously occupied by the disease. She had a continuous rise of temperature. After a time the skin lesions improved greatly, many of the areas disappearing entirely. The improvement continued for some months, when she was again admitted to the hospital in a condition somewhat similar to that previously described. It was discovered then that she was addicted to frequent fits of alcoholism, and developed a cirrhosis of the liver. She left the hospital, but died a few weeks later.

In comparing the two cases, their striking clini-

[1] Brit. Journ. of Dermatol., March, 1903.

cal resemblance is a noteworthy feature. In both cases there was a general toxemia of intense grade. In the one case a virulent toxin circulating in the blood caused an acute inflammatory disturbance in the skin; while in the other case alcohol is looked upon as the toxic element, which gave rise to a more chronic form of dermatitis.

THE URINARY CONSTITUENTS IN PSORIASIS.

Von Zumbusch[2] examined twenty-one cases with reference to the excretion of nitrogenous constituents and of uric acid. He notes that a number of observers, especially in England, have considered that there is a connection between psoriasis and uric acid diathesis. In fact psoriasis has been by some called gout of the skin, and the urinary analysis has been brought forward as a proof of this.

Others have declared that there was a relationship between psoriasis and diabetes, and numerous observers have described the urea and uric acid as increased in this disease. It is to be noted, however, that exactly opposite statements are made by other observers. The twenty-one cases examined by Von Zumbusch were all males, and were taken at varying stages of the affection. No internal medicine had been given before the investigation in any case. The cases are related quite fully, and the table of the results of the examination is appended. The result of this examination was a completely negative one, that is to say, it was found that the total nitrogenous constituents and the uric acid had not varied at all in amount from what we find in health. Furthermore, the quantity and specific gravity varied in no way from the normal. No relationship was found to exist between the severity of the disease and the contents of the urine.

MULTIPLE SPONTANEOUS KELOID.[3]

The conclusions of this article, which consists of a careful survey of the literature and report of a typical case, are as follows:

(1) By the name "keloid" is understood a special affection of the skin which, in many respects, resembles a neoplasm, and which, for the present at least, is to be included among the fibromata.

(2) Only the so-called primary and secondary keloids belong to the keloid group. The hypertrophied scar must be sharply separated from them.

(3) Both the clinical and the histological appearances prove that the division of keloids into primary and secondary has no justification, as both of these kinds of keloid are developed according to the same type of scar process. Nevertheless, such a division may be retained on clinical grounds.

(4) The histological changes in keloid are produced by an increased growth of connective tissue, with simultaneous disappearance of the elastic tissue along the course of the blood vessels.

(5) The histological differences between primary and secondary keloids, which were formerly accepted (especially the retention of the papillary layer in true and its disappearance in false), can no longer be considered valid.

(6) The etiology must be regarded as obscure.

(7) As chief cause of the development of keloid, a particular personal, family or race disposition must be assumed whereby the skin reacts to often slight irritation by the formation of keloid. In this way the tendency of keloids to recurrence is explained.

(8) The vascular system unquestionably plays a prominent part in the development of keloid.

(9) Keloid is neither a scar nor a simple hyperplasia of the connective tissue, and differs also in its formation from the infectious granuloma and fibromata, although its exact classification is at the present moment impossible.

(10) The cause of the spontaneous cessation of the growth of keloids is unknown.

(11) The prognosis of keloids is, in general, unfavorable.

(12) The treatment of keloids demands much time and is, on the whole, a rather thankless task.

A CASE OF SYSTEMIC BLASTOMYCOSIS.

Ormsby and Miller[4] report a case of this disease from the laboratory of Drs. Hyde and Montgomery in Chicago. The patient was a Swede, fifty-six years old, a machinist. He had never been very strong, and for years had lived over a stable, where the odor was at times almost unbearable. The first evidence of the illness which ended fatally was in the lungs, and made its appearance about eight months before his death. Two months later a lesion appeared on the skin of the outer part of the right thigh, which ulcerated and discharged. A month later another lesion developed on the right side of the nose. At this time he was pale, emaciated and anemic. There were also at this time several subcutaneous nodules; the temperature varied from 100° in the morning to 103° in the evening. Physical examination of the lungs showed bronchial breathing and other signs of pulmonary disease. From the subcutaneous abscesses pure cultures of blastomycetes were obtained before death, and from a considerable number of tissues and internal organs postmortem. Only one of the lesions assumed the usual characteristics of this disease; but this fact was owing to the rapidity of the process, in all probability. The lesions continued to increase in number, and at the time of his death the body was practically covered with lesions, varying from small superficial crusted ones on the face to ulcers of a large size on the extremities. He was treated with Koch's new tuberculin without reaction. Postmortem examination showed the lesions completely filled with miliary abcesses and tuberclelike nodules. The pleura were filled with nodules. The liver was extensively filled with miliary abcesses and nodules. The kidney was also affected, but not so extensively. The spleen was extensively affected so that some parts of it were practically destroyed. The mesentery was filled with nodules. In all these organs blastomycetes were demonstrated, both by the microscope and by cultures, in many cases existing in the form of a practically pure culture. Repeated examinations of these various tissues for tubercle bacilli were negative. Especial attention was given to

[2] Zeitschr. f. Heilkunde, 1902.
[3] Tschlenow: Dermatol. Zeitschr., April, 1903.
[4] Journ. of Cutaneous Dis., March, 1903.

this point, as the symptoms would suggest tuberculosis of the lungs. Guinea pigs were inoculated with the tissue, but none developed tuberculosis. The microscopical examination of the skin lesions showed that the lower part of the corium had been invaded in some places; but most of the infiltration was confined to the subcutaneous tissue. This infiltration was made up of enormous numbers of the organisms, together with leucocytes, red blood cells, plasma cells, mast cells and giant cells. In many instances the organisms were seen in giant cells. Numerous budding forms were everywhere seen.

The writers conclude that although the early lung involvement and other symptoms, such as the laryngitis and the microscopic appearance of the organs, all suggested tuberculosis, the latter affection may be ruled out by the absence of the tubercle bacilli, culturally, miscropically and experimentally, by the negative tuberculin reaction, the absence of the usual microscopic structure, the failure to produce tuberculosis in animals, the large number and rapid evolution of the skin lesions and the abundance of blastomycetes found in each lesion.

BLASTOMYCOSIS IN ENGLAND.

Sequeira[5] reports the first case of this affection in England, although he admits that his case differs from those described in America in many particulars, and that possibly the organism found may be of a different species.

The patient was a strong, healthy man of thirty-seven, who had never lived out of England. At one time he was employed at a brewery and had had a good deal to do with cattle. A little over a year previously he had noticed a small white spot, the size of a pin's head, just below the inner canthus of the left eye, which had increased and spread inwards. About five months after the first lesion appeared, a precisely similar one was noticed below the right eye, which had also progressed in the same manner until the lower lid was so much swollen that vision became difficult. Several other similar lesions appeared in the vicinity. A stained specimen of the discharge from one of the tumors showed the presence of yeastlike bodies. The patient was put upon iodide of potash in 5 and later in 10 gr. doses. There was little improvement until the drug had been increased to 105 gr. a day, when the lesions began to diminish rapidly. Ultimately the lesion under the left eye almost completely disappeared, while that under the right eye was less than half its original size. The patient was then lost track of.

Microscopically, there was found to be a great increase in the epidermal layer; the horny layer was thickened in places and contained numerous small abcesses; the deeper layers of the epidermis were thickened, and there was considerable down growth into the corium. In the corium there was a considerable infiltration of round cells; and in some of the sections there were giant cells. The yeastlike bodies were visible in the abcess cavities. The pus that was squeezed out from one of the growths showed pus cells, a few eosinophiles, a large number of cocci and yeastlike bodies. They were ovoid, with a well-defined margin and a double contour. They were seen both singly and in pairs, and in some the formation of buds was well marked, and in some instances there was a short chain formation. Unfortunately the organisms could not be cultivated, which he regards as due to the fact that the lesions examined were already infected with cocci. The organism found in this case is much smaller than those found in the American cases. He bases his diagnosis of blastomycosis on the fact that the face and scalp alone were affected, that the lesions were multiple and fresh lesions appeared apparently by innoculation, that the edges were well defined, with but little infiltration, and that they soon became pustular. Furthermore, there were numerous minute abscesses which were discovered under the microscope, which contained budding, yeastlike organisms. The fact that the deeper layer of the epidermis extended downward into the corium and that the growths were much influenced by large doses of iodide of potash also tends to strengthen the diagnosis.

LIGHT TREATMENT IN LUPUS.

Morris[6] begins with a résumé of the principles on which the Finsen method is based, namely, that light acts as a stimulant of organic life, which has been proved by experiments on the movements of animals; that this stimulating property has been shown to exist generally in the actinic or chemical rays of light; also that the chemical rays have the property of causing inflammation of the skin, as dermatitis from the sun and from electric lights has been proved to be caused by the actinic rays. It has also been proved that light has bactericidal properties, and that this increases in direct proportion to the degree of concentration of the rays. It has also been shown that light can penetrate the skin. With regard to lupus, Finsen's method has become a well-established method of treatment in most parts of Europe. In Finsen's latest statistics he claims 94% of successes and only 6% of failures. These statistics are more favorable than those from most other sources. Favorable results have also been reported in lupus erythematosus, alopecia areata, and in epithelioma.

Turning now to his own results, Morris asserts that while not so brilliant as those of Finsen, they have been satisfactory in a considerable number of the cases of lupus so treated. The larger part of the more extensive cases are still under treatment, and require a short course of treatment from time to time when new nodules make their appearance. In most of the cases in which a complete cure is claimed the diseased area has been of small extent. In the severe cases treated it is asserted that relapses are becoming fewer and the interval between them much longer. Of 65 cases of lupus, 11 have remained without relapse for from six months to two years. In 10 favorable cases of small extent, he thinks himself justified in saying that there has been a complete cure. In two cases in which there was extensive ulceration, the Finsen method proved useless; while in both there was rapid healing under the x-rays. A number of cases in which the disease was in the mucous membranes responded favorably to the Finsen treatment. Of 11 cases of lupus erythematosus

[6] The Practitioner, April, 1903.

there was great improvement in 7; in 1 there was a speedy relapse as soon as the treatment stopped. Of 27 cases of rodent ulcer favorable results are reported in 15. In most of these, however, the x-ray treatment was combined with that of Finsen. Relapse shave, however, occurred in most of them.

Morris asserts that it is better to restrict the term "Finsen light" to the particular way in which he applies the treatment, which differs from other methods in concentrating or focusing the rays before they reach the skin. It is on this principle that the original Finsen lamp is constructed; and according to Finsen, concentration is necessary in order to obtain the full effect of the light. In the French lamp of Lortet and Genoud there is no such focusing, and hence the penetration of the light is not so great. Morris thinks that the original Finsen lamp gives the best results on account of the greater intensity and penetrating power of the concentrated light. Among the disadvantages of this mode of treatment may be enumerated the great length of time required, the tediousness of the treatment for one hour daily, the occasional pain and the expense. Its advantages, however, are its excellent cosmetic results and its trustworthiness, as improvement may be expected in all cases, provided sufficient time is allowed. Under unfavorable conditions may be mentioned excess of pigment and thickness of the skin, great depth of the disease, scarring from previous treatment and great vascularity of the parts. The light treatment may also with advantage be combined with other methods, such as the x-ray; and where the disease is very extensive or there is much infiltration, curetting should be applied first.

Morris then relates five cases in which this method was employed, giving photographs of the patients both before and after treatment. In some of them the x-rays were used in combination.

Reports of Societies.

AMERICAN ORTHOPEDIC ASSOCIATION.

SEVENTEENTH ANNUAL MEETING, HELD IN WASHINGTON, D.C., MAY 12, 13 AND 14, 1903.

LOUIS A. WEIGEL, M.D., of Rochester, N. Y., President.

FIRST DAY.—TUESDAY, MAY 12.

EXCISION OF THE KNEE FOR BONE ANCHYLOSIS. REPORT OF A CASE.

DR. A. J. STEELE of St. Louis reported this case, one in which cuneiform osteotomy had been done. It was necessary to sacrifice the femoral epiphysis, but good osseous union was obtained. Nails were used in the first instance to secure proper fixation of the bones, and subsequently a well-fitted leather case.

DR. JOEL E. GOLDTHWAIT of Boston reported a series of similar cases, all of which had been treated by a wedge-shaped exsection. In these cases much difficulty had been experienced in maintaining a good circulation when the limb was straightened, apparently because of implication of the vessels in cicatricial tissue. In one case the circulation became so impaired that gangrene rapidly developed, necessitating an amputation.

DR. A. J. GILLETTE of St. Paul said that according to his experience, anchylosis in cases of tuberculous disease of the knee was rare. With forcible correction he found no occasion for tenotomy.

THE ABUSE OF FLAT-FOOT SUPPORTS.

DR. W. R. TOWNSEND of New York presented this paper. He called attention to the general increase in the use of flat-foot supports, partly owing, no doubt, to free advertising in the lay press and the sale of such supports in department, shoe and instrument stores. This general interest in the subject would be gratifying were it not for the present tendency to ignore the necessity for a correct diagnosis in cases of flat foot before applying such support. A support was not always required even though flat-foot were present; moreover, the existence of extreme spasm, deformity or inflammatory conditions might make the use of a support worse than useless. Many of the supports sold were so flimsy as to be utterly incapable of giving support, and not infrequently the support was applied so far forward or backward as to have no effect in preventing deformity; indeed, it often caused deformity and disability. He wished to specially emphasize the impossibility of treating all cases of flat foot in a routine way by ready-made supports and without skilled advice and supervision.

DR. GOLDTHWAIT called attention to a class of cases of rigid or extreme valgus which had proved obstinate to treatment by flat-foot plates. Quite recently he had learned to recognize these cases as examples of talipes valgus instead of varus, and they had responded readily to treatment for valgus, that is, excision of the scaphoid and shortening of the inner side of the foot, followed by correction.

THE SURGICAL PATHOLOGY OF GENU VARUM AND GENU VALGUM.

DR. WALLACE BLANCHARD of Chicago read this paper. He said that the skiagraphic observation of genu varum usually showed three contributing curves, which, in the order of their development, were: (1) An exaggeration of the normal out-curve of the lower part of the femur; (2) an outward bending of the upper part of the tibia; and (3) distributed outward bend of the shaft of the tibia. The curve in the upper part of the tibia generally became most pronounced. The least over-correction was required at the culminating point in order to give straight and lengthened legs. In genu valgum the primary inward bending was usually in the upper part of the tibia, and a succeeding inward curve became distributed through the shaft of the tibia. The least over-correction was required at the apex of the tibial deformity. Lorenz and Renier claimed that epiphysiolysis corrected by attacking the seat of the deformity in the condyles, but it had been shown that the operation was founded on a pathological error. Several of Renier's illustrations showed opening of outer knee articulations without indications of separation of the epiphyses or of fractures, and the result was apparently the same as in Lorenz' recently discarded operation of over-stretching of the external hamstring tendon.

In the operations of this kind that he had done there had been so much reaction that he had not felt justified in continuing to practise it. His own method of rapid osteoclasis he considered decidedly superior, and that either this or osteotomy should be preferred to epiphysiolysis.

THE MECHANICAL VERSUS THE OPERATIVE TREATMENT OF RACHITIC DEFORMITIES OF THE LOWER EXTREMITIES. A STATISTICAL REVIEW.

DR. R. TUNSTALL TAYLOR of Baltimore was the author of this paper. To show the superiority of operative treatment he quoted their statistics, that is, 109 cases with only two relapses and one over-correction. In this connection he exhibited a very ingenious, and apparently effective, osteoclast that he had devised. The distinguishing feature was that it worked on the lever principle, and was constructed to give very rapid and accurate results.

DR. AUGUSTUS THORNDIKE of Boston remarked that the new instrument impressed him favorably because it appeared to imitate closely the natural process of producing a fracture.

DR. JOHN RIDLON of Chicago, from the standpoint of one who had invented and had used a similar device, suggested that a round or elliptical bar be substituted for the flat one, and that if the leather covering were discarded, and bare, polished metal bars be used, there would be less danger of lacerating the skin.

DR. HENRY LING TAYLOR of New York called attention to the twist of the shaft of the tibia occurring in most cases of bow-legs, and advised that, in operating, one should give the lower fragment a strong outward twist.

THE TREATMENT OF PARALYTIC TALIPES BY TENDON TRANSPLANTATION SUPPLEMENTED BY OTHER OPERATIVE PROCEDURES.

DR. ROYAL WHITMAN of New York presented this paper. He said that the results of the operation of tendon transplantation at present were unsatisfactory, the favorable effects of the operation often being only temporary. This was often due to the correction of deformity and the removal of a deforming force rather than to a permanent gain in muscular power. Simple operations, in which both the positive and negative effects of transference of muscular power could be utilized should be selected, and the attachment of transplanted tendons to those of the paralyzed muscles should be replaced by direct implantation at a point of election. Periosteal implantation was less effective than that to the bone itself. Secondary operations, such as arthrodesis of the mediotarsal joint for the prevention of varus or valgus deformity, and astragalectomy, were often indicated, or, indeed, imperatively demanded.

DR. J. E. GOLDTHWAIT said that by tendon transplantation it often became possible to make use of lighter braces. In some of these cases a double pull was established by reason of a cicatricial formation in the old sheath of the tendon.

ACUTE ATROPHY OF BONES AND JOINTS FOLLOWING COMPARATIVELY SLIGHT INJURIES.

DR. JOEL E. GOLDTHWAIT of Boston was the author of this paper. He said that slight injuries were often followed by long impairment of function of the affected part, and not infrequently by permanent disability. The active stage was characterized by subacute swelling, pain on motion, and, at times, by an appearance not very unlike a tubercular process or rheumatoid disease. X-ray examination showed general atrophy of the bones and joints of the part, thus explaining the permanent disability.

DR. WHITMAN remarked that as bone was living tissue, there was no need to invoke the action of the trophic nerves in order to explain the atrophy.

DR. STEWART L. MCCURDY of Pittsburg said that the atrophy was dependent upon a lesion of the sympathetic rather than of the cerebrospinal system.

DR. L. A. WEIGEL said that this atrophy, which was eccentric, could only be positively diagnosticated by the x-ray, but there was often a peculiar cadaveric coldness of the part which was quite characteristic.

EARLY OPERATIVE TREATMENT OF TUBERCULAR OSTEITIS OF THE KNEE.

DR. BERNARD BARTOW of Buffalo read this paper. He said that localization in the early stage was generally limited to the femoral epiphysis. The existence of an epiphyseal focus of disease could often be determined before the occurrence of joint infection, but when the joint had once become invaded excision should be substituted for protective treatment. In carrying out the early operative treatment, search should be made for the focus by trephining the condyle above the capsular attachment. When diseased tissues were found, they should be curetted away, the cavity treated with carbolic acid, iodine or chloride of zinc, and the operation wound closed by suture. Severe flexor contraction should be relieved by open division within the tendon sheaths, and fixation secured by plaster of Paris. After healing of the wounds locomotion might be allowed with the aid of crutches and a high shoe. If excision should be indicated at any time, it could, of course, be performed with the same chances of success as if the foregoing procedure had not been undertaken.

SECOND DAY. — WEDNESDAY, MAY 13.

SOME POINTS IN THE TREATMENT OF HIP JOINT DISEASE.

DR. GEORGE B. PACKARD of Denver read this paper. The author considered the time traction and fixation should be continued, for, he said, he had long been impressed with the retardation of growth incident to interference with functional use. The advantage of massage and protected use of the limb after the acute stage was passed was dwelt upon, and emphasis was laid upon the general treatment, particularly the dietetic. It was recommended that these children should have three substantial meals a day, and that each of these meals should be followed by a glass of milk and a raw egg.

OBSERVATIONS ON HIP DISEASE AS SEEN IN HOSPITAL OUT-PATIENTS.

DR. AUGUSTUS THORNDIKE of Boston was the author of this paper. While admitting the unsat-

isfactory character of out-patient treatment, the author insisted that the results obtained contrasted well with recent statistics on hip disease from abroad. An analysis was then given of 55 cases coming to the Children's Hospital Out-patient Clinic, nine, ten and eleven years ago. Of these 55 cases, 17 had the disease in the right and 36 in the left hip, while 2 were double. The first five years of life furnished 51.7%, the next five years 42.6% and the period between ten and twelve years of age 5.5%. The shortest duration of treatment was four years, and the longest treatment was now over eleven years. In all but six of the cases the Taylor long-traction splint was used. Prolonged recumbency was not employed. Abscesses were present in 42% of the cases, and in 3% of these abscesses were incised, curetted and drained. The average shortening amounted to 1⅓ inches. The results were considered good, although falling a little short of those achieved in some other hospitals in this country.

HIP DISEASE, CONSIDERED WITH SPECIAL REFERENCE TO THE COMBINED TREATMENT.

DR. R. TUNSTALL TAYLOR of Baltimore presented this communication as a continuation of the one presented a year ago. He reviewed the methods already advocated, and dwelt upon the great value of the skiagraphic diagnosis as contrasted with tuberculin, and upon the choice of cases, the method of disinfecting the joint after erasion and the subsequent treatment. Having lost one case from carbolic acid poisoning, he had substituted formalin for carbolic acid. A series of cases were reported upon, and the skiagraphs of the same exhibited; also two patients. The author was firmly convinced of the value of the *combined* treatment which he advocated, and believed that exploratory incisions would often clear up the diagnosis, serving to differentiate between septic and tuberculous conditions. The patients were kept in bed for six or eight weeks with traction in abduction, and were then allowed up and around for about one year with traction splint and high shoe. He thought Lorenz was right in his statement that Americans were inclined to overdo the restraint of the functional use of tuberculous joints. He was of the opinion that the x-ray would aid the surgeon in determining the proper time for tentatively allowing functional use.

DR. BERNARD BARTOW of Buffalo, in opening the discussion on the foregoing papers, said that, while good climatic conditions were of advantage, it should not be forgotten that perfect fixation was essential to success. He strongly indorsed the line of treatment advocated in the paper of Dr. Taylor.

SIR WILLIAM HINGSTON of Montreal was also thoroughly in favor of early operation, having been long convinced that the treatment of a child for an indefinitely long period by extension was an error.

DR. G. G. DAVIS of Philadelphia said that he had frequently made a number of small trephine openings in the head of the bone in cases of acute tuberculosis of that part, and while this had cut short the acute symptoms, and in a number of instances had apparently been completely successful, yet in time the symptoms had reappeared, emphasizing once more the truth of the old doctrine that, in this disease, it was necessary to rely largely upon rest to effect a cure.

DR. V. P. GIBNEY of New York advocated cutting down upon the points of infiltration, evacuating their contents and suturing the wound without drainage and without the use of chemical agents. A skin-fitting plaster bandage and an ice bag should then be applied, and the child kept at rest for several days. The subsequent progress of the case could be followed by skiagraphs, and in this way a useful guide obtained as to the amount and duration of the traction.

DR. NEWTON M. SHAFFER of New York said that the initial limp was the danger signal, and at all times weight-bearing was the true test of whether or not it was safe to discard apparatus. When in doubt, it was safer to err on the side of the too prolonged use of apparatus.

DR. CLARENCE L. STARR of Toronto said that two or three years ago he had advocated early curettage, followed by swabbing with pure carbolic acid, and a continuance of this practice had not been attended by carbolic acid poisoning in any instance. The use of alcohol after the application of carbolic acid seemed to him to distinctly favor the absorption of the acid, by dissolving away the wall of coagulum first formed by the acid.

DR. E. H. BRADFORD of Boston objected to Dr. Taylor's recommendation that when there was much detritus the surgeon should cut down and remove it on the ground that the hip could not be treated the same as the knee or ankle. Experiments conducted in the pathological department of the Harvard Medical School had demonstrated the fact that the x-ray did not serve as a reliable guide to the limits of the disease.

DR. B. S. MCKENSIE of Toronto said that Dr. Taylor was working in the right direction, but should be cautious not to exceed the limits of true conservatism. In his own city the orthopedic surgeons had obtained the very best results from having their patients in the hospital kept in tents all the year.

DR. TAYLOR, in closing, pointed out that the anterior incision passed through the intermuscular septum down to the capsule, thus doing the minimum of damage to the tissues.

THE CORRECTION OF DEFORMITY AT THE HIP THE RESULT OF DISEASE. A STUDY OF THE BEST METHODS AND BEST POSITIONS.

DR. V. P. GIBNEY of New York presented a paper with this title. He raised the question as to whether the disturbance of the reparative process occasioned by forcible correction under an anesthetic might lead to a recurrence of the disease, and expressed the opinion that the Gant operation was the safest and most effective operation for appropriate cases. It was unsafe to resort to forcible correction where sinuses led down to the joint. It had been asserted that forcible correction caused the development of tuberculous meningitis, but available statistics did not seem to bear out this assertion. He was strongly of the opinion that osteotomy should be done by the subcutaneous method, and that the ability to sit comfortably should be sacrificed to the ability to stand and walk erect.

DR. A. J. STEELE of St. Louis cited a case in

support of the view that the use of extreme force in correction was liable to lead to the development of tuberculous meningitis.

DR. JOHN RIDLON of Chicago placed on record five cases operated upon last fall by the Lorenz method, in all of which the deformity had remained corrected and the extent of motion varied between 5° and 10°.

DR. J. E. GOLDTHWAIT placed on record sixteen cases, operated on during the past winter.

DR. NEWTON M. SHAFFER said that so many disastrous results had followed forcible correction in advanced cases that he was not yet convinced of the propriety of this procedure.

THE FORCIBLE REPOSITION OF CONGENITAL LUXATION OF THE HIP.

DR. C. G. DAVIS of Philadelphia read this paper. He expressed the opinion that the methods employed in the past had been unnecessarily severe, and it was desirable to follow more closely the original lines laid down by Paci. The use of the more recent methods had been accompanied by severe traumatism, paralyses and even death. It was obviously inappropriate to style a method "bloodless" which caused the formation of hematomata of such size as to extend from the middle of the thigh to the umbilicus. It was best to attempt the reposition by the gradual and careful manipulation advised by Paci, aided, if necessary, by the subcutaneous division of the adductors, and if this failed, instead of resorting to extreme force, employ weight extension in bed, with the limb abducted until reduction was possible without the use of excessive force. Or, it might be well in difficult cases to incise and clear a way for the head to enter the acetabulum.

CONGENITAL DISLOCATION OF THE HIP. REPORT OF A BLOODLESS REPOSITION FOLLOWED BY DEATH, WITH AN ANALYSIS OF TWENTY-THREE CASES IN PROCESS OF TREATMENT.

DRS. H. AUGUSTUS WILSON and J. TORRANCE RUGH of Philadelphia presented this paper, together with a pathological report by DR. W. M. L. COPLIN. The patient was a girl of seven years with a double congenital dislocation of the hip. She was in fair condition, and a radiograph showed conditions favorable for replacement. Reduction by the Lorenz "bloodless" method was undertaken at the Jefferson Medical College Hospital on March 18, 1903. All associated in the treatment of this case had been intimately connected with the eight cases reduced by Lorenz on Dec. 11 and 12, 1902. The fifth and sixth hips reduced by Lorenz were extremely difficult, but finally yielded to his experienced and skillful manipulations. Thirteen hips were subsequently reduced at the Jefferson Hospital, and two more outside. There were 12 girls and 5 boys, 6 being double. Of the single, 8 were right and 3 left. The youngest patient was twenty months; 6 were under two years; 2 were between two and three years; 5 were between three and four years of age; 5 were between six and seven years; 3 were between eight and nine years, and 2 were ten years old. In the case forming the subject of this report, a child of seven years had been under treatment elsewhere since the age of two years, and until within a few days of the operation. At the latter very great difficulty was encountered in reduction, far greater than in a boy of ten years with double dislocation. Complete, satisfactory reposition could not be obtained, and fixation in the "frog position" by means of plaster of Paris was done, intending to do a cutting operation later. The anesthesia lasted one hour and twenty minutes, and 3½ oz. of ether were consumed. Complete consciousness returned after the operation, only to be followed by a mild delirium, then collapse, which was partially recovered from, and eventually by death in twenty-two hours. The postmortem examination was performed by Dr. Coplin, who found that a long and large ligamentum teres more than filled the acetabulum, and was the cause of the failure in effecting reduction. The articulating surface of the head of the femur rested on the posterior and upper edge of the acetabulum; the capsule was elongated and thickened, and there was a fracture of the femoral neck, one of the body of the ischium and one of the ascending ramus of the ischium. The ends of all the bones were in close apposition. In addition, the pathologist found an acute catarrhal bronchitis, and acute catarrhal pneumonia and an acute diffuse hemorrhagic nephritis.

THE RESISTANCE OF TISSUES AS A FACTOR IN THE MANUAL REDUCTION OF CONGENITAL HIP DISLOCATIONS.

DR. E. H. BRADFORD of Boston presented this paper. He stated that the practical use of the method was limited by the surgeon's power and the strength of the resisting tissues. Variations in the surgeon's strength might be disregarded in estimating the problem, but the other factor was of great importance. The force necessary to tear the insertion of the tendo Achillis was often beyond the limits of practical surgery, and the danger in the use of great force on strongly resisting tissues was manifest in the irreducible cases of congenital hip dislocation. Tenotomy of the tendo Achillis was of recognized utility, and while tenotomy of the hamstrings and adductors had been used in these cases, the procedure did not possess great value. Lorenz' method for children between the ages of three and six was satisfactory. As a result of an anatomical study he had reached the conclusion that the chief resistance came from the strong tendon of the adductor magnus, and that this could be overcome by a tenotomy at some distance from the hip, thus rendering unnecessary the employment of great force. It was found that the lower fibers of the adductor magnus were collected together into a strong tendon, which could be readily divided. The chief factor in transposition was apparently the torsion of the femur.

(To be continued.)

FOOT AND MOUTH DISEASE. — It is reported that foot and mouth disease has been completely stamped out in Massachusetts, and it is probable that the quarantine will be completely raised within two weeks.

SIGNED EDITORIALS.

AT the recent meeting of the American Medical Editors Association, held at New Orleans in May, Dr. T. D. Crothers of Hartford, Conn., read a paper in which he discussed the shortcomings of the editorial pages of our medical journals. Quoting the scepticism with which ether as a means of anesthesia was at first discussed by medical men through their journals and their frequent unjustifiable criticisms of work which later has been proved to be of scientific value, he maintains that any study of the editorials in our present-day journals continues to show traces of this same "narrow, assertive dogmatism."

He finds that advances in medicine are not always reflected in the editorials, and that the editorial matter as a rule is not of the same quality as the original articles. He thinks further that editors write superficially, that they misjudge the power of discrimination of the readers, that many phases of medical practice are discussed with small knowledge and appreciation. He also finds fault with what he calls "personality in journalism," and sees in the various attitudes of our medical editors a just cause for criticism. As a remedy for all this and various other faults, which he regards as apparent, he thinks that all editorial comment expressing definite personal opinion should be signed.

Apparently this point of view has been accepted by one of our contemporaries, the combined *New York and Philadelphia Medical Journal*, whether stimulated or not by this paper of Dr. Crothers' we have no means of knowing. In the last issue of this journal two of the editorials on points of practical importance to the physician are signed by their authors. In justification of this somewhat radical editorial policy, the journal speaks in part as follows:

In this issue of the journal we begin the publication of "signed editorials." Those of our readers who are strict of diction may object that there can be no such thing as a "signed editorial"—that a signed article is necessarily not an editorial. Well, we are disposed to concede a good deal to strictness of diction, and we will admit at the outset that we use the term "signed editorial" simply for the sake of convenience, without in the least pretending that it is satisfactorily expressive. Still, our readers may perhaps be willing to admit that a signed article may have a certain degree of editorial quality if we let them into the secret of the fact that we are in great measure editorially responsible for these signed articles; that is, that we share the responsibility with the writers, which we do not profess to do in the case of other contributions bearing the authors' names, but, on the contrary, quite disclaim doing.

We certainly see no harm in applying the principle of individual authorship to editorial comment, but we confess that the argument advanced by our contemporary does not seem to us wholly satisfactory. The mere fact that the editor agrees with statements made by another man and holds himself editorially responsible is rather an evasion of the issue. In medical matters, should any question be raised, it is clear that in the eyes of the profession at large the responsibility must ultimately rest with the author of a signed article. We take it that it is because of this fact that the universal custom in journalism, whether medical or lay, has come to devote certain pages to unsigned statements, thereby giving added dignity to its utterances, and also, we are willing to admit, at times permitting superficiality of treatment, as Dr. Crothers has suggested.

In general we are inclined to think that the accepted method is the better one, and that communications to retain their editorial character should remain unsigned. If this be true in lay journalism, we see no reason why it is not equally applicable to medical journalism. Dr. Crothers' strictures are certainly in a measure justified, but we cannot accept his conclusion that the matter would be remedied by the free use of individual signatures. It is certainly desirable to improve our editorial pages as such, to guard against personalities, to be fair to our contemporaries and to maintain an increasingly higher standard, but this should, and may in our opinion, be accomplished by a continuance of the time-honored system.

THE MANILA DEATH-RATE.

THE report of the commissioner of health for the Philippines, Major E. C. Carter, surgeon U. S.

Army, for the month of March last, is of particular interest, since it calls attention to the gratifying and progressive decrease in the death-rate for Manila, as shown by comparing the vital statistics for the first three months of each of the past four years. Figured for each month on a basis of the deaths which would occur at the existing rate in each 1,000 population for one year, the figures are as follows:

	1900.	1901.	1902.	1903.
MONTH.	An. death-rate per 1,000.	An. death-rate per 1,000.	An. death-rate per 1,000.	An. death-rate per 1,000.
January	50.65	36.22	30.16	23.46
February	47.08	36.69	30.81	22.05
March	42.67	42.67.	30.02	21.01
Av'ge annual death-rate for period compared . . .	46.80	38.19	30.33	22.17

It is seen from these figures that so far during the present year the Manila death-rate is less than half what it was for the same period four years ago. Based on present estimates of population, the number of lives which may be expected to be saved in 1903, judging from the first three months of this year, as compared with the same period in 1900, will amount to 7,442.

During the first quarter of the present year the death-rate has been reduced by 27%, as compared with the rate existing for the same period twelve months previously. This latest improvement has been accomplished in spite of the fact that Asiatic cholera and bubonic plague had both previously gained a foothold in the islands, and that the existence of a largely unvaccinated population in the provinces meant a constant introduction of smallpox into the city. Cases of plague, cholera and smallpox have occurred in Manila in each of the above months of the present year, but the precautions taken by the Board of Health prevented any epidemic outbreak as a result of these cases.

The sanitary results attained in the past four years through American control have been accomplished in spite of the naturally unsalubrious location of Manila, and its total lack of sanitation under Spanish sovereignty. Its level site interfering with drainage, the many foul canals extending through the city, the absence of any sewerage system, and the existence of an impure and insufficient water supply and of many old, unhealthful habitations, have all combined to create sanitary problems of the greatest difficulty. The Board of Health has been unable to turn previously existing methods and conditions to sanitary advantage, and has found it necessary not only to develop entirely new plans of improvement, but at the same time to combat the results of inherited unsanitary conditions. The mixed character of the population, Americans, Spanish, Filipinos, Chinese and others, and the prejudices, superstitions and largely primitive habits of life of the latter classes, have been a constant obstacle to sanitary work.

The report invites attention to the fact that the Manila death-rate so far during the present year, 22.17 per 1,000, is lower than that of many cities in the United States and elsewhere, which are not commonly regarded as unhealthful. For the year 1900 the following are some death-rates useful for comparison: Washington, D. C., 22.80; New Orleans, La., 24.74; Atlanta, Ga., 23.01; Memphis, Tenn., 25.10; San Antonio, Tex., 27.01; Charleston, S. C., 34.94. The rate for Honolulu in 1902 was 25.59; the rate for Boston in 1900 was 20.12; and for Havana, Cuba, in 1901, it was 22.11.

These results attained in Manila are certainly remarkable, and reflect great credit upon the ability and energy of the Americans who have conducted the sanitary work. It is not probable that equally as low rates as in the first quarter can be maintained throughout the present year, in view of the slight increase in cholera certain to occur with the onset of the rains; but in the coming year, when both plague and cholera will probably have ceased to be factors in the death-rate, it is probable that the death-rate of Manila will compare favorably with those of the cities in the southern part of the United States. That such results as have already been attained could be brought about in four years in spite of every obstacle shows that the American sanitarians here are bearing their full share of the "white man's burden."

CHANGES IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

PRESIDENT BUTLER of Columbia University, at the recent annual commencement, commented upon the past and present status of the College of Physicians and Surgeons, now affiliated with the university as its medical department. He alluded to the fact that the institution had suffered through the increasing number of its students, and the consequently increasing lack of facilities for their proper instruction, and also to the need of readjustment of the curriculum in order to keep up with the progress of medical teaching.

In consideration of these facts he announced, as stated in the *Medical News*, that the faculty had decided to put in operation a new and thoroughly

revised curriculum, with a diminution in the number of didactic lectures and an increase in personal laboratory work in various medical branches. Increasing facilities will hereafter be given to physiology, and, as previously announced, an entirely new department of pharmacology and therapeutics will be organized under men of recognized prominence in that branch of work. The principle of individualizing the instruction will also find place in the work in pathology, so that not more than ten students will be assigned to any one laboratory instructor.

After commenting on the development of the Vanderbilt clinic, which has long been associated with the medical school, President Butler urged the necessity of a university hospital, an adjunct of medical schools which has been peculiarly slow in coming in this country. Another suggestion, which we regard as of very great importance, is that a reference library for students be provided at the medical school. This again is a need which has been slow of recognition. It would certainly be possible to organize and equip such a library with the more important medical books and periodicals to which students should have free access, and there can be no question that such a library close at hand would prove as valuable a stimulus to students of medicine as do libraries in other departments of knowledge to students of those branches. Finally, President Butler expresses the hope that with a raised standard of admission to the medical school there may be this year a diminution of the number of students applying, and that this diminution will take place among those least competent.

All this sounds familiar. The stimulus which for various reasons has been given to the cause of medical education, within the last few years, is gradually finding expression in all our large medical institutions, and will, no doubt, by degrees have its effect upon the smaller ones. Large financial resources are evidently necessary in order that these complicated schemes of instruction may be carried out. It is gratifying in this connection to note that President Eliot, whose judgment of the trend of contemporary events is not likely to be at fault, recently remarked, as stated in another column, that "the money" (speaking of the medical school) "comes easier there than anywhere else. . . . It is directed in this way by the conviction that many more discoveries and unimagined blessings are coming out of medical study into the service of the world."

If this be true there can be no question that the future of medical education, and the best medical education, is assured. We are glad to note that the College of Physicians and Surgeons of New York is coming to a clear recognition of the needs of the immediate future, since it is eminently desirable that our leading medical institutions should unite in their claims as to what the definite requirements are, of the most progressive medical school. That the necessary money will be forthcoming to meet this general demand, recent events bring absolute assurance.

MEDICAL NOTES.

DEATH OF PROF. CARL GUSSENBAUER. — The death of Prof. Carl Gussenbauer of Vienna is announced in the sixty-second year of his age. He was formerly one of Billroth's assistants, and after holding various professorships in other universities, he was in 1894, on the death of Billroth, called to Vienna as professor of surgery. In 1895 he became an editor of the *Archiv für klinische Chirurgie*. His contributions to medical literature have been numerous and on most diversified topics in relation to the general subject of surgery.

DEATH OF PROF. CARL GEGENBAUER. — The death of Prof. Carl Gegenbauer, at one time professor of anatomy in the University of Heidelberg, is announced at the age of seventy-six.

RECORD OF CHICAGO HEALTH DEPARTMENT. — In reply to an attack on the Chicago Health Department made in certain of the Chicago daily papers, Commissioner of Health Arthur R. Reynolds makes a vigorous defense in the *Bulletin of the Health Department* and submits the following figures: During the six years 1891–1896, immediately preceding the present administration of the department, a total of 152,424 deaths were reported in Chicago; during the six years 1897–1902, of the present administration, the total deaths reported were 145,907, or 6,517 fewer deaths in upwards of 360,000 more population. The reduction is even greater among infants and young children — the acknowledged test of the efficiency of a sanitary administration. During the first period there were 68,008 deaths under five years of age; during the second period there were only 49,360 such deaths.

BOSTON AND NEW ENGLAND.

CHANGE OF EDITORIAL OFFICE. — The editorial office of the JOURNAL will hereafter be Room 707, Paddock Building, 101 Tremont Street. MSS. and communications to the editor should be sent to this address.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 15, 1903, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: Diphtheria 30, scarlatina 18, typhoid fever 18, measles 20, smallpox 0.

CHILD LABOR. — The American Federation of Labor has taken up the question of child labor and has presented an appeal for a stricter enforcement of the law, particularly in certain districts in Lowell. It is stated that many children under fourteen are at work in the mills.

FURTHER GIFTS TO THE HARVARD MEDICAL SCHOOL. — In his speech at the commencement exercises of Harvard University, President Eliot said: "This year our treasurer reports that the cash addition to the property of the college is $1,300,000. Of that sum $500,000 consists of contributions to the great undertaking of the medical school. And that leads me to speak of this particular direction of the beneficence of the friends of the university — for medicine. More than $2,000,000 have been attracted to the medical school undertaking. The money comes easier there than anywhere else. What is the reason? It is directed in this way by the profound sense of gratitude of many men and many women for the service which medicine has rendered to them, to their children, to those dear to them. It is directed in this way by the conviction that many more discoveries and unimagined blessings are coming out of medical study into the service of the world. This very day there have been added to the funds provided for the medical school undertaking $285,000. And both gifts — there are two — come charged with the most sacred purpose to do good in this world."

WORK OF BOSTON DISPENSARY. — At a recent meeting of the managers of the Boston Dispensary, it was reported that the total of new patients treated at the dispensary during the last quarter was 9,902, and that the number of visits made by district physicians at the homes of patients was 5,036. Ninety-three physicians are now connected with the institution, and about 15 special departments of medicine are reported. With the growth of the institution, in spite of the recent enlargement of the building, there is still lack of room for the best work. An additional building is needed at a cost of $65,000, and there is also need of funds to provide districts in Charlestown and Dorchester, in order that patients may be treated at their homes. The Boston Dispensary is doing a somewhat unique work and one which all who have information on the subject know to be of the greatest value to the community. It is to be hoped that the necessary expansion of the work may not be hindered for lack of financial support.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending July 11 was 202, as against 190 the corresponding week last year, showing an increase of 12 deaths, and making the death-rate for the week 17.46. Of this number 102 were males and 100 were females; 126 were born in the United States, 73 in foreign countries and 3 unknown; 40 were of American parentage, 139 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 34 cases, 1 death; scarlatina, 21 cases, 2 deaths; typhoid fever, 19 cases, no deaths; measles, 23 cases, no deaths; tuberculosis, 20 cases, 24 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 15, whooping cough 1, heart disease 17, bronchitis 1, marasmus 3. There were 24 deaths from violent causes. The number of children who died under one year was 39, under five years 56, persons over sixty years 41; deaths in public institutions 60.

NOTES FROM THE PHILIPPINES.

VACCINATION. — During the first three and one-half months of this year the vaccine farm of the government laboratories has issued 750,257 units of vaccine virus. During the previous three months 162,221 units were thus issued, making 912,478 units distributed in about six months. The present increase in the output of vaccine virus is due to the development of smallpox through the provinces, and the effort of the Board of Health to vaccinate the entire population of the islands as soon as possible. The latter task, herculean under the best conditions, is rendered even more difficult by lack of proper transportation, which renders the progress of the vaccinators through the islands unduly slow, and also is a cause of annoying delays in supplying them with virus. The fact that there are so many tribes in the islands, with entirely different ideas, customs and languages, also complicates the situation. As the sanitary machinery gets in better condition over here, the work will go on more rapidly. The city of Manila is now thoroughly vaccinated, and the work has about come to an end. During the present outbreak there have been only thirty-eight cases of smallpox in Manila, with six deaths, a fact that speaks volumes for the efficient way in which the health authorities have carried on their work. This small number of cases will compare very favorably with the amount of smallpox in the cities of the United States of the same size, and especially those largely having a dark-skinned population. Manila has a large floating population, and with the provinces as yet insufficiently gone over by the vaccinators, it is

inevitable that the infection should be introduced by unvaccinated individuals from time to time. Smallpox has been especially severe in the Igoriote country and in the smaller southern islands, where whole communities were swept away before the health authorities were able to control the epidemics by vaccination. Fortunately this is one of the few sanitary measures to which the native is not seriously opposed, and one which does not depend upon his own exertion for its performance. Any measure which calls for labor on the part of the native population has been shown by experience to be rarely properly carried out.

DESTRUCTION OF UNSANITARY HOUSES. — The Board of Health is destroying many unsanitary native houses in its operations against plague, but as the infected houses are usually tumble-down shacks of flimsy materials, appraised on an average as having a value of $10 or $15 each, no very great pecuniary loss results. These houses are drenched with coal oil and burned under charge of the fire department. As the new houses erected on their sites must be approved by the sanitary engineer of the health department, and as the further erection of nipa and bamboo houses in certain districts of the city is prohibited, the destruction of each house means not only a temporary but permanent sanitary improvement of the city.

IMPORTATION OF CARABAO. — Bids have already been opened for 10,000 carabao to be sent to the Philippines to replace those lost from rinderpest, the Government proposing to expend $1,000,000 for the purpose of restocking the islands. Most of the animals will be imported from southern China and Saigon, and all will be immunized with rinderpest prophylactic serum before embarkation. Thorough inoculation is absolutely necessary to the success of the plan, as many of the cattle ships are undoubtedly infected with rinderpest, and the disease is so prevalent in many parts of the islands that to ship the cattle without treatment means almost certain death to them. In the work of immunization so far carried on, only 5% of the animals have been lost, and if that ratio can be maintained in the future the officials in charge will feel fully satisfied. A part of the appropriation of Congress for the islands has been set apart to pay for the work of immunization. At present, the facilities for inoculation are not so complete as is desirable. Animals afflicted with the disease are necessary for the work of preparing the serum, and the sixty animals from which the material for inoculation has been obtained are now so thoroughly immunized that they are no longer of value for the purpose. The Board of Health is making strong efforts to keep new rinderpest infections from gaining entrance to the islands, and all cattle ships are now disinfected by the marine hospital surgeons at the Mariveles quarantine. At present, cattle ships are inspected by a board of veterinary surgeons before they are allowed to discharge their cargo. The animals are isolated in corrals near the water front and kept under observation prior to slaughter. No animal is permitted to leave the yards for any other purpose than slaughter without receiving an anti-rinderpest inoculation. A large quarantine camp for cattle is projected, and will probably be located at Malabon, six miles from Manila. The best place for the cattle quarantine is at Mariveles, but at that place it would be necessary to re-load the animals on boats for Manila and the provinces, and the added expense inclines the officials to regard the site at Malabon with more favor.

ATTEMPT TO SAVE CARABAO FROM RINDERPEST. — The health department of the Philippines has met with many unusual experiences in its sanitary work in the archipelago, of which its efforts to save the carabao on the island of Tablas from rinderpest furnish a good example. Last year, when this disease was killing the cattle and carabao herds throughout the larger islands, inoculators with anti-rinderpest serum and apparatus for the immunization of these animals were sent to Tablas. The disease at that time had made scarcely any progress there, and the natives, with characteristic dread of new ideas and with distrust of the vaccinators, objected to having their cattle and carabao inoculated. It was tried on a few animals almost by force; and when these animals developed the slight illness which follows inoculation, a wave of indignation swept over the island. Carabao were hurried into the mountains and hidden so that they might be kept from the evil influence of inoculation. The inoculators explained and pleaded, but all in vain; and when they threatened to forcibly inoculate the animals they were met with a like threat, and were warned that if they followed the carabao to the mountains they would be mobbed and killed by the aroused natives. Open threats were made, and the government inoculators were practically forced to flee from the island after having inoculated but twenty carabao. In due time the wave of rinderpest reached Tablas and the animals began to die. Hundreds perished from the disease, but not one of the twenty that had been given the mysterious treatment of the Americanos. The immunized twenty browsed and fed and wallowed with the other carabao, but were not affected. When all was over the twenty were about the only survivors from rinderpest left on the island, and as time passed the business end of the proposition finally penetrated to the brains of the natives and over-

came their superstitions and prejudice. A few days ago a very humble delegation of residents of Tablas presented itself to the government authorities in Manila, and requested that an expert with a barrel of anti-rinderpest serum be sent to their island to treat the few remaining animals and those that they were importing.

Miscellany.

RESOLUTIONS ON THE DEATH OF W. D. HOLMES, M.D.

THE Fellows of the Norfolk South District Medical Society hereby express their regard and esteem for their deceased colleague:

Dr. Holmes, although a recent member of our society, did not hesitate to express his opinion in our deliberations, our actions, our discussions, and that too in a manner suggestive of ripeness, deliberation and thought. Many of us had met him professionally but little, during his short residence in Braintree, and yet those in his immediate vicinity who had, always found him the true physician, the courteous, unselfish, professional gentleman, the tried and trusted guardian of his patients, his friends.

The members of this society offer to his wife and family their heartfelt sympathy in their deep affliction, and to that larger circle who have lost their warm, sincere and sympathetic adviser, our condolence at this time.

Resolved, That this memorial be entered upon the records of this society; that a copy of the same be forwarded to Mrs. Holmes, and that a copy also be furnished for publication to the Braintree papers and to THE BOSTON MEDICAL AND SURGICAL JOURNAL.

Respectfully submitted,

For the society,

HENRY L. DEARING, M.D.
ROBERT F. BURLEIGH, M.D.
FRANK W. BRETT, M.D.

Correspondence.

ARE NURSES PROFESSIONAL PERSONS?

BOSTON, July 5, 1903.

MR. EDITOR: Your editorial in the current number of the JOURNAL (July 2) must interest all of us who have concerned ourselves with what one may call the nurse's problem. One aspect of the problem frequently has appeared to me to be too little regarded; I refer to the condition which you mention in describing the work of nurses as a "liberal profession,"—their status after graduation.

The meaning of the words "liberal profession" must be an extremely elastic one. The Standard Dictionary defines a profession as "an occupation that properly involves a liberal education or its equivalent, and mental rather than manual labor." Truly this is a halting description, though correct enough so far as it goes.

I take it that professional persons, such as lawyers, doctors, literary men, engineers, etc., work for fees — for small fees or for large fees according to their earning capacity. The professional person's success in life must depend upon his mental and physical achievements and capacities, and his tasks, limited in the same fashion, are a measure of his success.

In this sense can nurses be regarded as professional persons? In the very nature of things they must work for wages and not for fees, their wages are limited by well-recognized conventions and their ambitions and progress are not stimulated by increasing opportunities and proportionate increasing returns.

Most of the advocates of the higher training of nurses have lost sight of the individual after her graduation. It would be interesting to know in what way they propose to solve the problem of nurses as practitioners and not as undergraduates..

School work is but the first step in the career of most professional persons. After graduation comes development, progress, achievement. In every true profession there must be ceaseless advance, but no goal.

Who may say that in a nurse's life work, her graduation does not mark the goal of progress?

M.

APPENDICOSTOMY?

BOSTON, July 3, 1903.

MR. EDITOR: With the interrogation mark preceding this word, after the manner of the Spanish, it simply says what is the expense attached to my appendix? It would be a wise plan to appoint a philologist on the surgical staff of every hospital and as the surgeons invent new operations the decadence of the classics could at the same time be avoided.

It is not plain to me how this word can come to signify the procedure which your editorial describes. If, as you admit, the word is a hybrid, then it is part Latin and part Greek while wholly English. I cannot translate the "cos" unless it means rib. It is to be supposed that the usual τομή extends to the ribs then? But why do you allow Meyer to continue that surgical falsehood that the appendix is "an absolutely useless organ," in the light of the numerous investigations already published which show that this is a very important organ which "actively functionates"?

It is very poor logic which allows the conclusion that because we do not know what an organ does we must infer that it does nothing.

I rather discourage your attempt to award a palm to a surgeon for a discovery which no chirurgeon (worker by hand) can ever make unless at the same time he is a good physiologist. Will you not write for us a timely editorial upon the true function of the appendix? It will, at least, encourage the farmers who have had very poor luck with their grape culture since our lamented Jackson so earnestly told us that its only function consisted in "catching grape seeds and giving typho-enteritis."

Very truly yours.

EDMUND D. SPEAR, M.D.

METEOROLOGICAL RECORD.

For the week ending July 4, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

Deaths reported, 3,447; under five years of age, 1,234; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,066, acute lung diseases 300, consumption 333, scarlet fever 41, whooping cough 36, cerebrospinal meningitis 8, smallpox 12, erysipelas 11, measles 35, typhoid fever 55, diarrheal diseases 443, diphtheria and croup 83.

From whooping cough, New York 8, Chicago 2, Philadelphia 9, Baltimore 2, Pittsburg 3, Boston 1, Worcester 1, Fall River 3, Lowell 2, Cambridge 1, Springfield 2, Woburn 1, Beverly 1. From erysipelas, New York 3, Chicago 2, Philadelphia 3, Pittsburg 1, Boston 1, Everett 1. From smallpox, Philadelphia 8, Pittsburg 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending June 20, the death-rate was 14.3. Deaths reported, 4,138; acute diseases of the respiratory organs (London) 134, whooping cough 99, diphtheria 42, measles 136, smallpox 7, scarlet fever 38.

The death-rate ranged from 4.7 in Hornsey to 28.7 in Coventry; London 13.1, West Ham 12.2, Brighton 10.0, Portsmouth 12.6, Southampton 8.0, Plymouth 14.4, Bristol 11.7, Birmingham 17.1, Leicester 13.0, Nottingham 16.1, Bolton 13.8, Manchester 18.9, Salford 12.9, Bradford 13.6, Leeds 15.3, Hull 16.9, Newcastle-on-Tyne 17.4, Cardiff 17.5, Rhondda 13.9, Liverpool 17.8, Great Yarmouth 15.1.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 9, 1903.

GASSAWAY, J. M., surgeon. Leave of absence granted Surgeon Gassaway for two days from June 28, amended so as to be effective from July 5. July 3, 1903.

STONER, G. W., surgeon. To proceed to Richford, Vt.; Malone, Niagara Falls and Buffalo, N. Y.; Montreal, Canada; Port Huron, Detroit and Sault Ste. Marie, Mich., for special temporary duty. July 8, 1903.

DECKER, C. E., assistant surgeon. Granted extension of leave of absence, on account of sickness, until July 15. July 7, 1903.

TROTTER, F. E., assistant surgeon. Granted leave of absence for seven days. July 6, 1903.

MCLAUGHLIN, A. J., assistant surgeon. Assigned in charge of Miscellaneous Division, Bureau of Public Health and Marine Hospital Service. July 8, 1903.

ROBERTSON, H. MCG., assistant surgeon. Granted leave of absence for five days. July 3, 1903.

CHANDLER, R., acting assistant surgeon. Granted leave of absence for eight days from July 18. July 8, 1903.

CLEAVES, F. H., acting assistant surgeon. Granted leave of absence for twenty-three days from July 6. July 2, 1903.

PRIMROSE, R. S., acting assistant surgeon. Granted leave of absence for ten days. July 2, 1903.

WIGHTMAN, W. M., acting assistant surgeon. Granted extension of leave of absence for one week from June 26. July 2, 1903.

BOARD CONVENED.

Board convened to meet at Washington, D. C., July 8, 1903, for the purpose of considering the preparation of plans for the inspection of vaccine farms and anti-toxin establishments. Detail for the board: Assistant Surgeon-General H. D. Geddings, chairman; Passed Assistant Surgeon M. J. Rosenau; Passed Assistant Surgeon J. F. Anderson, recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JULY 11, 1903.

R. L. SUTTON, assistant surgeon. Detached from Naval Hospital, Washington, D. C., and ordered to Baltimore, Md., for special temporary duty.

O. KOHLHASE, assistant surgeon. Ordered to Naval Hospital, Mare Island, Cal.

W. H. RENNIE, assistant surgeon. Ordered to Naval Hospital, Naval Home, Philadelphia, Pa.

W. B. SMITH, assistant surgeon. Ordered to Naval Hospital, Pensacola, Fla.

J. S. WOODWARD and P. T. DESSEZ, assistant surgeons. Ordered to Naval Hospital, Navy Yard, Washington.

J. D. MANCHESTER, assistant surgeon. Ordered to Naval Hospital, Navy Yard, Boston, Mass.

A. J. GEIGER, W. S. HOEN, assistant surgeons. Ordered to Naval Hospital, Navy Yard, Norfolk, Va.

C. E. RYDER, J. A. RANDALL, assistant surgeons. Appointed assistant surgeon with rank of lieutenant, junior grade, from June 26, 1903.

J. T. MILLER, acting assistant surgeon. Ordered to Navy Yard, Mare Island, Cal.

F. W. TYREE, acting assistant surgeon. Appointed acting assistant surgeon with rank of lieutenant, junior grade, from July 1, 1903.

S. H. DICKSON, medical inspector. Granted sick leave for three months.

G. R. PLUMMER, acting assistant surgeon. Appointed acting assistant surgeon with rank of lieutenant, junior grade, from July 1, 1903.

H. N. T. HARRIS, surgeon. Detached from "Glacier" and ordered home to wait orders.

F. W. F. WIEBER, surgeon. Detached from Naval Academy and ordered to wait orders.

BOOKS AND PAMPHLETS RECEIVED.

Uric Acid as a Factor in the Causation of Disease, a Contribution to the Pathology of High Blood Pressure, Headache, Epilepsy, Nervousness, Mental Diseases, Asthma, Hay Fever, Paroxysmal Hæmoglobinuria, Anæmia, Bright's Disease, Diabetes, Gout, Rheumatism, Bronchitis, and Other Disorders. THE SHATTUCK LECTURE.

THE SOURCES, FAVORING CONDITIONS AND PROPHYLAXIS OF MALARIA IN TEMPERATE CLIMATES, WITH SPECIAL REFERENCE TO MASSACHUSETTS.*

BY THEOBALD SMITH, M.D., BOSTON.

(Continued from No. 3, page 64.)

WHATEVER may be the biological process, to us its significance is summed up in the possibility of infecting the mosquitoes.†

Without doubt the parasites are so few in the blood in the clinically recovered or the immune cases that only a small percent of the attacking Anopheles would infect themselves. The most favorable time for such infection would be at the end of a relapse or a fresh infection, when a large number of the parasites would become gametes and thereby capable of continuing the cycle in the mosquito. The attacking mosquitoes would at this stage find plenty of gametes and the danger of creating a focus would be at its maximum. It will be seen that I am putting the burden of starting new foci of malaria and of awakening the disease in the spring upon the older, latent or partly immune cases, who are in that stage of immunity which readily produces gametes after a relapse.

The transmission of sporozoa seems to be accomplished chiefly through the agency of recovered cases. *Coccidium oviforme* of rabbits is handed down from parents to young. This is probably the case with one form of bird malaria due to *Halteridium danilewskyi*. Some years ago I examined in this vicinity the blood of four young crows belonging to the same brood. In one of them the malaria parasites were very numerous. The others were not infected. I examined the blood of the infected bird day after day without seeing any forms indicating multiplication. When a drop of this blood was examined with high powers of the microscope, a considerable number of the largest parasites would rupture the red corpuscle in about two minutes and a half, assume the form of spheres, and throw out a number of flagella. The parasites were all gametes or becoming such.‡ The infection of the young bird which had not yet left the nest came probably from the parents through some ecto-parasite. In their blood the parasite was probably in a "latent" condition.

The surest way of testing the infectiousness of persons freshly attacked, those who have passed through several seasons of malaria and those who have grown up where malaria is endemic, is to determine from what class of cases mosquitoes can infect themselves. It should also be thoroughly ascertained to what extent infection is possible in the latent stage. Experiments made for this purpose by endeavoring to infect mosquitoes have been reported from various countries. The precise history of the cases from whom mosquitoes drew blood is not given and in most instances the experiments were made in localities more or less permanently under the influence of malarial virus. Bignami and Bastianelli refer to a patient with crescents in his blood who successfully infected *A. claviger* and *A. superpictus*. Grassi succeeded in infecting Anopheles from a patient whose blood was full of crescents. W. S. Thayer[29] reported in 1900 a slight infection of *A. maculipennis* after feeding on a case of tertian and one of estivo-autumnal fever. Woldert[30] writes of one infection after many negative trials with the estivo-autumnal parasite. Similarly, Berkeley[31] refers to one infection out of sixty dissections. Van der Scheer and Berkelom[32] in an endemic locality in Zealand (Denmark) found that they were able to infect Anopheles when the blood contained gametes, but not when quinine treatment had preceded the experiment. Manson's[33] son was successfully infected with mosquitoes imported from Italy which had fed upon the blood of a case of benign tertian fever.

It is evident that the infection of mosquitoes is not an easy matter and frequently fails. These failures may be in part due to the mosquito, but I am inclined to believe that they are largely due to the patient not being ready to furnish satisfactory gametes. Grassi[3] (p. 115) makes the significant statement that "there are persons who though their blood contains gametes are not capable of infecting Anopheles. These gametes . . . are sometimes too young, more often they appear too old, or perhaps the suspected parthogenesis which leads to relapses has already been started." It is quite obvious that the large amount of painstaking work which has been done in studying the transmission of malaria is only the beginning of more detailed and thorough work to be done not only in the tropics but in those localities in our climate where malaria is trying to obtain a foothold, but has not yet fully succeeded.

The persistence of the malaria parasite in the blood explains not only the dissemination of malaria by human beings, but it also throws a strong light upon the many theories formerly held concerning the source of malarial infection. The so-called hydric theory which regarded bad drinking water as a source of infection is quite prevalent in the South. When a person drank bad water, upset his digestive system and had an attack of malaria as a result, the inference that the water introduced the germs was a natural one. We know, however, that such digestive disturbances simply give the latent virus an opportunity to multiply by temporarily breaking down protective barriers, as shown by the exhaustive statistical studies of Caccini. Summing up the evidence concerning human beings as carriers of malarial parasites and as sources of infection, we find that there is no definite information at hand as to the time when affected individuals may infect mosquitoes. Data from various sources including comparative pathology favor the view that human beings are not at once infectious, but that this capacity comes with prolonged parasitism and that it may be retained indefinitely.

* Delivered before The Massachusetts Medical Society, June 9, 1903.

† To me the simplest explanation which has suggested itself is that during the period of latency the parasites multiply as they do during the clinical outbreak, but more and more slowly, and in fewer numbers. Each sporulation is drawn out, in time as it were, and leads finally to the formation of gametes.

‡ The asexual stage of this parasite is not known.

MOSQUITOES AS INTERMEDIATE HOSTS OF MALARIA.

To follow the intricate processes of the immunization of man during malaria, and their bearing upon infectiousness of the patient, can have only a secondary value with us, even if it were possible to say at what precise moment the mosquitoes may become infected by drawing blood. The healthy individual, even though dangerous, should not be restrained if the suppression of malaria can be accomplished in other ways. This leads me to the second link in the etiological chain — the mosquito. The relation of mosquitoes to malaria as carriers became a definite working hypothesis with me in 1896. In 1897 I devised a set of questions for use in the investigation of local epidemics, among which those concerning mosquitoes and the relative exposure of individuals to them were prominent. The hopelessness of making any progress in this subject, in a latitude usually free from malaria and only sporadically invaded by it, soon became evident. The sequel showed the reasonableness of this state of mind. Not a single fact of fundamental importance in the etiology of malaria has been discovered outside of the endemic foci, and the most valuable studies have been made in the heart of the tropics. There are, however, minor problems pertaining to local conditions which can be solved perhaps better in our latitude than farther south.

Basing ourselves upon the work of Grassi and those who have followed him, we include only the genus Anopheles among the intermediate hosts of the malaria parasite. In our State two species of this genus are widely disseminated and encountered in many localities. These are *A. maculipennis* and *A. punctipennis*. The introduction of these species into Massachusetts is not known. They are, however, not a recent acquisition. Dr. C. S. Minot[34] found larvæ identified by Mr. Burgess as Anopheles in ponds of the Forest Hills district in 1880. Which species they represented is not known. By far the most prevalent and most numerous species is *A. punctipennis*. It is as large as the large Culex species, and is particularly conspicuous on account of the yellowish-white spots on the wings and its peculiar position when resting. The adult female, leaving its hiding places in the early spring, measures (excluding proboscis) 5 to 6 mm. in length. The life history differs only in unimportant details from that of the genus Culex. The aquatic larvæ, after a period of two or more weeks, depending upon the temperature and food supply, enter the pupa stage. In this they remain about three days and then emerge as sexually mature insects. *A. punctipennis* may be encountered on the wing from March until late in November. In 1902 I encountered a number of females on March 22, when they vigorously attacked me. In 1903 they did the same thing, March 14, a very warm day. Even in midwinter they may be seen about houses when they have been driven from their hiding places by workmen.

The larvæ, as is now well known, differ from those of Culex in lying horizontally just below the surface of the water, with the short air-tubes on the eighth abdominal segment at the surface. They vary more or less in coloration from a light to a dark green. White dots along the dorsal median line of the abdomen may or may not be present. The largest are about 6 to 7 mm. long. During the summer of 1902 I spent much time in the effort to find some means of distinguishing the larva of *A. punctipennis* from that of *A. maculipennis*, but thus far without success. This may have been in part due to the fact that the latter were quite scarce. The pupæ of the two species of Anopheles differ very slightly from those of Culex. The shorter breathing-tube in Anopheles, as mentioned by Howard,[35] has served me well in recognizing them.

A. punctipennis I have found either in the larval or the adult form in different parts of our State. The larvæ were taken to the laboratory, and there the development into the adult insect was watched in order to make sure of the species. In this way I have collected or bred *A. punctipennis* from various regions of the Boston district (Forest Hills, Jamaica Plain, West Roxbury near Charles River, Faneuil Station, Cambridge, Belmont), Weston, Concord, Clinton, South Lancaster, Pittsfield and Williamstown. They have been found in Worcester and Springfield. I am inclined to believe they will be found breeding in all parts of our State, if diligently looked for.

A. maculipennis, according to my observations, is a less common species. It is distinguished from Culex with greater difficulty, owing to very slight spotting of the wings. In its position also it differs less from Culex than does *A. punctipennis*, and I have been deceived several times at a distance in confounding it with Culex. I have already referred to the difficulty in distinguishing it from *A. punctipennis* in the larval stage. This species has been collected from Greater Boston. It was found very abundant, in the fall of 1901, near the Charles River in West Roxbury (Parental School). Among specimens sent me from Concord by Dr. Chamberlin, some years ago, this species was included. Only very few of the insects I have bred in the laboratory were *A. maculipennis*. This may be due to their relative scarcity or to the difficulty of rearing them artificially, as some larvæ usually die. It is of interest to note that in certain localities certain species or groups of species seem to predominate. In the fall of the year when mosquitoes are driven indoors by the cold, in search of places for passing the winter, I have noticed that in one building almost exclusively individuals belonging to the genus Culex would appear. In another building, an eighth of a mile away, individuals of *A. punctipennis* were found almost exclusively. In a third place, three or four miles away, *A. maculipennis* was the predominant species. In a suburb of Harrisburg, Pa., in August, 1900, Bashore[36] counted 133 *A. maculipennis* and 7 *A. punctipennis*. The conditions favoring the breeding of these species may throw an important light upon the endemicity of malaria in certain places. Thus far they have not been thoroughly studied, and they remain unknown.

It is now generally conceded that all species of Anopheles may become intermediate hosts of the malaria parasites. But some are much more easily infected than others. Of the two prevalent in Massachusetts, *A. maculipennis* (*A. quadrimaculatus*, *A. claviger?*) is the one which has been chiefly experimented with in other countries. I am not informed of any experiments with the commoner *A. puncti-*

pennis. Some test of this important matter under conditions and with Anopheles existing in our latitude is very urgent. We should know the relative capacity of the two species for maturing the tertian parasite as drawn from the infected individual. We should know more about the temperature limits within which this development may go on to a successful conclusion. Since such experiments can now be carried on without exposing human beings to infection, by simply dissecting the infected mosquitoes, there is no reason why this information should not be forthcoming. We are in many respects better situated than those commissions who have made their investigations in tropical and subtropical countries, because we have but one parasite, that of tertian fever, to deal with, while their work has been complicated by the prevalence of three forms.

The application of knowledge gained in tropical countries, while applying in general to our own conditions, may fail in what are biologically speaking minor details, but practically speaking of very great importance. Outwardly and to the entomologist, *A. maculipennis* of our climate and that of Italy or the tropics may be the same.* But there may be important physiological differences due to climatic conditions. Marked differences in susceptibility toward certain diseases may exist in varieties or breeds of higher animals. Similar varietal differences could hardly be detected in mosquitoes by the classifier. Experiments to determine definitely the rôle of our two species of Anopheles in transmitting malaria are called for the more pointedly since voices have been raised recently against the assumption that all Anopheles species act as carriers. Christophers and Stevens found that the very abundant *A. rossii* in and about Calcutta did not convey malaria. When they proceeded in their investigations toward the foothills of the Himalayas, foci of endemic malaria appeared associated with other species of Anopheles shown to carry sporozoites in their salivary glands. Schüffner[9] in studying Anopheles on Sumatra, where malaria prevails chiefly on the coast, came to the conclusion that the coast mosquito soon degenerates in inland regions owing to unfavorable environment.

The mosquito, like the higher animals, appears to be the victim, or at least the host, of a number of parasites, belonging to widely different genera. In 1901, H. P. Johnson,[59] working in my laboratory upon Anopheles caught in the Charles River district, found in about 10% of the individuals of *A. maculipennis* bodies on the stomach wall which simulated very closely the malaria parasite. A very careful study, however, led to the decision that it was some other sporozoon, probably a gregarine.

The breeding places of Anopheles in our State are, as a rule, small, more or less stagnant bodies of water. They do not appear to breed in water kept in receptacles such as rain barrels, tin cans, street traps, obstructed house gutters and the like, but only in water collecting on the ground. But once I saw many Anopheles larvæ in rain-water which had collected in a large iron scoop; but even this was in a country district. This choice of natural bodies of water may account for the fact that Anopheles with us is essentially a rural insect so far as its breeding habits go. Occasionally it has been found in slightly brackish water,[37] but it is essentially an inhabitant of fresh water. It is stated that the insects prefer sunny places, but I have seen them in well-shaded brooks.

The food of these larvæ consists of minute forms of life floating in the water, and chiefly algæ and protozoa. The larva during feeding turns its head 180° so that its ventral surface is directed upward. The two brushes begin to swing rapidly. Currents are produced and the minute particles suspended in the water are violently thrown toward the mouth of the larvæ. They are thus dependent upon food floating near the surface layer of water. As is well known, ground water emerging into the light is rich in those salts which greatly favor the rapid growth of algæ, and E. O. Jordan[38] has found during observations made in Maine that such ground water contains Anopheles larvæ.

The wide prevalence of these larvæ in the country does not indicate any very great fastidiousness on their part, or any easily determined conditions which must prevail if they are to succeed. Among the places where they are found with us I may mention a few.

In low-lying rich meadows, with very little slope, the ditches used for drainage frequently contain Anopheles larvæ. Where foot-bridges cross them collections of rubbish are likely to form quiet pools for them. In larger brooks, Anopheles larvæ are encountered in pools formed by obstructions in the bed, such as tree stumps soil carried down during freshets and rubbish thrown into them. Especially where roads cross them, the aqueducts are apt to become dilapidated. Fallen stones and pieces of wood form artificial barriers here to favor the mosquitoes.

Not infrequently small shallow pools of rain or ground water without any outlet are favorable breeding places. These are frequently the result of insufficient or obstructed drainage due to road building and railroad embankments. The railroads are in fact responsible for many breeding places. Not only has the natural drainage been more or less interfered with by the construction of embankments across drainage valleys, but the soil used for such embankments has often been taken in such a manner as to leave ditches filled with stagnant water on one or both sides.

The larger bodies of water, including ponds, lakes and rivers, are not as a rule breeding places of mosquitoes. The enemies of the larvæ seem to predominate in such waters or else the food

*The position of the two last segments of the palpi in the male of our *A. maculipennis* is at right angles to the body axis and directed laterally. The figures of the European species, as given by Nuttall and Shipley[62] Kerschbaumer,[60] Grassi and Celli,[61] have the male palpi nearly straight and nearly in the body axis.

supply is too limited. Occasionally the shallow margins densely overgrown with water plants may favor them, but even here I have as a rule failed to find any larvæ.

The influence of sewage pollution upon the immunity of the larger bodies of water, more particularly the rivers (that is, the shallow margins, coves and stagnant reaches), is an important, though as yet unrecognized, question of public sanitation. It has been my personal experience to find larvæ in several badly polluted streams and not in those comparatively free from such pollution. Whether we are dealing here with a general fact or an accidental coincidence, I am still unprepared to say. Yet there is food for reflection and further study in the suggestion. Water polluted to a certain degree may favor the food of mosquitoes and suppress their enemies. Without going into any detail concerning my observations and impressions on this point, I leave it for future investigation.

Abandoned canals have in some states formed the focus of malaria infection, and there can be little doubt that they are admirably suited as mosquito breeders. Another variety of nuisance is created by brick manufacturing. Excavations are made for clay, and these are abandoned to themselves after the available material has been removed. Some years ago, in trying to account for cases of malaria in Southborough, I found in company with Dr. C. P. Jones a series of depressions overgrown with vegetation and partly filled with standing water. Mosquito larvæ were abundant in some, absent in others. We could not account for these depressions until told that they were old clay pits. A few broken bricks found near them afterward confirmed the statement.

The relation of shallow, stagnant pools and of small brooks and ditches to the mosquito varies considerably with the season and the rainfall. A certain abundance of rainfall may produce breeding places on the one hand, while on the other it may destroy such places already in existence by flooding and washing them out. To take a simple illustration: In 1902 a brook which during the greater part of the summer contained a moderate amount of running water did not harbor any mosquito larvæ. Late in August the amount of water in it decreased, and its bed consisted of a series of pools with only a little running water. In September I found the stream now containing many larvæ of Anopheles flourishing in the disconnected pools. Here the dry weather favored the mosquitoes. In other parts the dry weather had caused the shrinkage and disappearance of stagnant, undrained pools, which earlier in the season contained many larvæ.

Severe drought may favor them by a shrinkage and concentration of water in streams which may greatly favor the food supply of mosquitoes along the banks and in quiet, shallow coves. It may also disconnect shallow portions along the banks or shores from the main body and thus create breeding grounds where ordinarily none exist.

High temperature is universally favorable to the mosquito, for its larval life is shortened thereby and the food increased. It is also favorable to the rapid maturing of the malaria parasite in the mosquito. Under a certain temperature the parasite does not ripen.

There still remains one other condition of our surface waters which has been frequently considered the cause or at least the favoring condition of malaria. I refer to the impounding of flowing water artificially by dams. Only those who have explored our State more or less can have an adequate conception of the number of dams which have been built along its watercourses, and which have either been abandoned or which are still in use. To those familiar with the actual condition of things, an occasional examination of the map is a source of much interest. The streams, large and small, show a series of aneurysmal dilatations which might be considered freaks of nature, were it not that they are the work of man, and that originally beautiful streams have been defaced and deformed to yield the power needed to develop the factory industries of New England.

The site of a dam is usually chosen where its constuction will permanently flood the original banks and form a reservoir. The result is a settling basin, in which the suspended matter is deposited, slowly filling up the available space. The next step to offset this filling up is to raise the dam and flood more territory, thereby producing a still broader and usually very shallow basin.

The influence of dams upon the incidence of malaria will depend on a number of factors, and each dam must be considered by itself. The main factor is the relation of the dam to mosquitoes. Among the conditions which may favor the breeding of mosquitoes a few deserve special consideration:

(1) The shallowness of the water and the very gradual slope of the banks, which are usually densely overgrown with vegetation and which protect the larvæ from natural enemies.

(2) The relative pollution of the water, which on the one hand may stimulate the multiplication of microscopic algæ and other food for mosquito larvæ, on the other interfere with the higher animal life.

(3) The seasonal fluctuation, whereby in late summer detached pools and larger collections of water are left as mosquito breeders, provided the water in them does not dry up within three or four weeks.

The great dangers of such reservoirs has usually been ascribed to daily fluctuations of the water level, due to draining off during the working hours and refilling at night. The sloping sides of the reservoirs, formed of a deposit of very fine mud and ooze, are exposed to the sun during the day and in some unknown manner

malaria germs were supposed to rise from this alternately submerged and exposed mud. In many instances the original construction of the dam, or its subsequent elevation to a higher level, flooded woodland and the decaying tree stumps were looked upon as favoring or incubating malaria germs. To-day we interpret the matter quite differently. There is no evidence, experimental or theoretical, which assigns to malaria parasites life outside of man or the mosquito. They spend their whole life as parasites. Hence the exposed mud flats, though offensive, cannot any longer be regarded as the *causa peccans*, and the decaying vegetation is concerned only in furnishing food to pools of water harboring larvæ. Dams obstructing the normal current of any stream cannot thus be condemned without investigation. The particular local conditions must be taken into consideration and a careful search made for larvæ at different times of the warm season.

The salutary break in the continued breeding of mosquitoes, and hence in the accumulation of infection, by our severe winters, leads me to consider briefly the ways in which the mosquito escapes destruction during the cold season.

The hibernation or wintering over of adult mosquitoes has been known for many years. They seek the shelter of dark, unoccupied rooms and warm cellars, and the protected nooks in outhouses where they hide in a partly paralyzed condition until the warmth of the approaching spring stimulates them to move and leave their hiding places. It is surprising to note how many mosquitoes live through the winter in this way. Swarms appear quite suddenly on the first warm day. I have been unable to find among these any males.* The hibernating females are as a rule impregnated and very eager when they have left their hiding places to obtain food. Hence their vicious attacks at this time. The relation of these early attacks upon human beings to the production of malaria I shall refer to again later on. The wintering over of larvæ in water under the ice has been observed in different localities. Its occurrence in our latitude has not yet been reported, I believe, and I have no observations bearing upon this subject beyond the one that I have almost always failed to find larvæ late in the fall, shortly before the approach of winter.

The adult females which emerge in the early spring to obtain food for maturing the eggs have not been found with sporozoites in the salivary glands or with sporocysts on the stomach walls. The consensus of opinion seems to be that the malarial infection is not carried over in the mosquito, but that the latter is infected by drawing blood from cases having early relapses or a latent infection.

In concluding this chapter on the mosquito I shall merely mention the hypothesis occasionally brought forward that the infection may pass from the female mosquito to the ova and that the young may spread the germs. This complex process is the one which obtains in bovine malaria, and it is the only way in which the parasite can be transmitted; for the female which draws infected blood never passes to another host. No proof has been adduced in favor of this process in the mosquito; yet I think it should not be lost sight of or cast aside too peremptorily in any future work, for epidemiological studies do not contradict it.*

* I believe that the testimony is quite general that males have not been found hibernating.

THE HISTORY AND PRESENT STATUS OF MALARIA IN MASSACHUSETTS IN THE LIGHT OF RECENT BIOLOGICAL DISCOVERIES.

Interest in intermittent fever in our own State has been steadily maintained since the Boylston prize essay of Dr. Holmes. The disease has had more than its share of historians and chroniclers who have industriously labored to set before us accurate records of its dissemination and prevalence and who have attempted to locate the cause or causes.

As stated by Dr. J. F. A. Adams, there were several distinct epidemics of malaria in New England: (1) The earliest of which we have any records occurring among the settlers, especially in the New Haven region; (2) the epidemic of 1793–99 in Western Massachusetts; (3) that of 1828 to 1836, also in Western Massachusetts; and (4) the one beginning roughly in 1870 and continuing sporadically up to the present.

In Hubbard's "General History of New England," ague and fever is referred to as the "seasoning" through which newcomers had to go at New Haven in the earliest years of the colony. In the second epidemic, toward the end of the eighteenth century, the source of the infection in Massachusetts is, according to Dr. Holmes' correspondents, Western New York. The types of malaria are spoken of as quotidian, tertian, and quartan, and a type is described by Dr. Buel as occurring in the Sheffield epidemic in 1795 whose picture does not fit into the clinical frame of simple tertian. It suggests the estivo-autumnal fever of more southern latitudes. Yet it may after all have been a very severe type of tertian due to the presence of many generations of parasites. Buel calls it a bilious remittent fever. He emphasizes the pain in the head, back and limbs, the length of the hot fit as from six to forty-eight hours. There was no regularity in the reappearance of the paroxysms. "The fever tended to an intermittent form; but it could neither be called quotidian, tertian, quartan nor any other name used by authors to distinguish the different species of intermittent fevers." Possibly typhoid fever may have complicated the clinical picture. The immediate occasions for the appearance of the

* A large number of works on the mosquito have recently appeared in various languages. For those intending the more thorough study of species the work of L. O. Howard[35] forms a very good introduction. The largest and most recent monograph is that published in three volumes by F. V. Theobald under the auspices of the British Museum of Natural History. In this volume the reader will find references to other similar monographs. The work of Kerschbaumer[36] gives many interesting details concerning the life history of the mosquito.

disease were then as now assumed to be the construction of dams, the lowering and raising of the water level in them, and the building of canals. I find mosquitoes mentioned once in Dr. Holmes' essay as being more numerous than usual during the epidemic of intermittent fever and dysentery in the town of Sheffield in 1796.

Concerning the epidemic in 1828 to 1836, Dr. Oliver Peck of Sheffield writes, among other things, to Dr. Holmes that "the people here generally have a prejudice against the arrest of the disorder, imagining that they must have about a certain number of paroxysms at any rate, and that they are left more healthy if the disease is permitted to go on undisturbed, though bark was formerly and quinine is at present frequently used, and as I think with benefit. The disorder affects newcomers more especially, and more certainly the nearer they reside to the locality." In this letter we have a cropping out of the doctrine of immunity in malaria, already noted in the experience of the earliest settlers, who referred to it as the seasoning process. Dr. Holmes' correspondent was as eager then as now to impress upon him that the cases in his town were introduced and not indigenous. Relapses were clearly recognized, and some stated what is not an infrequent occurrence nowadays, that the recovered patient had a relapse early the following spring. Moreover, the influence of various bodily conditions due to intemperance, exposure and the like in bringing on a paroxysm was emphasized repeatedly.

The reappearance of malaria in more or less epidemic form since 1870 was carefully studied by Dr. J. F. A. Adams. He states that the summers of 1870, 1876 and 1880 were hot and dry, and all streams and ponds became extremely low. These seasons were characterized by an unusual prevalence and rapid spread of intermittent fever; in 1870 in New Haven and vicinity; in 1876 at Hartford and other towns on the Connecticut River in Connecticut; and in 1880 on the Connecticut River in Massachusetts and certain localities in Berkshire. The low water of 1880 was extraordinary. The Connecticut River had not been so low for many years, and all artificial reservoirs became drawn down so as to expose an immense area of marshy bottom. The irregular progress of the epidemic is also commented on. It jumped over certain places at first, to attack them later on.*

Intermittent fever around New Haven was described by Dr. H. Bronson[40] in 1872. The first case he traces to a sawmill in West Haven in 1863. The epidemic in South Framingham in 1885 has been investigated by Dr. Z. B. Adams[41] and described in a graphic manner. It seems to have been associated more or less directly with the building of a new conduit through Farm Pond.

* A somewhat similar survey of this last wave of malaria was published by Dr. C. V. Chapin. (The Origin and Progress of the Malarial Fever now Prevalent in New England. Fiske Fund Prize Dissertation. No. 32. 1884.)

Dr. C. H. Cook[42] in 1890 published an exhaustive inquiry into the prevalence of intermittent fever in Massachusetts. From 152 cities and towns responding to his circular letter, 86 reported intermittent fever, "an increase of 39 over the number reported in 1880 by Dr. Adams." Thirty-four towns reported sporadic cases only. In 52 the disease was more or less epidemic. In 1894 Dr. J. J. Thomas[43] collated information obtained from physicians and hospital records in towns along the Charles River, which showed a very great prevalence of malaria, especially in the town of Newton. The largest number of cases occurred in 1891–94, although in the years 1890 and 1891 the cases had been numerous. There are still two other papers dealing with the same theme whose authors made careful local inquiries. In 1901 Dr. F. L. Morse[45] investigated the prevalence of intermittent fever, past and present, in the towns bordering the Sudbury and Concord rivers. The earliest case of which he could obtain any definite information occurred in 1880, and is said to have been acquired in Boston. Among 1,186 persons, 209 cases occurred during the past twenty years.

A similar inquiry was made by Dr. Chamberlin[45] for Concord, for the period from 1870 to 1900.*

In addition to these various more or less exhaustive reports we have certain data collected by the State Board of Health in the routine examination of blood films for the malaria parasite. These data are valuable, since they are based on the demonstration of the parasite in the red blood corpuscles.

STUDIES ON THE ACTION OF ALCOHOL IN DISEASE, ESPECIALLY UPON THE CIRCULATION.[1]

BY RICHARD C. CABOT, M.D., BOSTON.

PERHAPS no subject has been more frequently or more heatedly discussed during the last few years than the action and value of alcohol. We have had two interesting symposia upon the subject in Boston within a year, and many similar discussions are reported in domestic and foreign journals. One might think, therefore, that the subject was about threshed out and that nothing new could be said about it, but as one looks over the reports of these discussions one fact is very striking, and that is the scarcity of experimental evidence regarding the action of alcohol in diseased human beings.

In the discussions to which I have referred, the disputants have usually ranged themselves in two parties, those favoring the use of alcohol on one side and those opposed to its use on the other. Those who favor its use usually do so on the ground of their general impression that it has done good in cases under their observation. Those opposed to the use of alcohol usually refer to a number of experiments, for the most part not very recent ones, upon the action of the drug in the lower animals. But very rarely has any one anything to say about experiments or measurements of the action of the drug upon any of the functions of the diseased human being. The "advocates of alcohol" say that it does good, but if you ask them: *What* good does it do? Does it decrease temperature? Does it improve sleep? Does it slow or strengthen the heart's action, and if so how much? — they have rarely anything to answer. On the other hand, if you ask the "opponents of alcohol" what harm it does they will point to the effect produced on a dog or a rabbit by doses of alcohol which would correspond to giving a man a quart of whiskey at a drink, or they will refer you to experiments on healthy soldiers or typesetters. The use of such evidence assumes that alcohol acts in the same way in all animals; whereas we know well that its action in mammals is very different from its action in birds, and have by no means proved what is true of its action in dogs or rabbits is true of its use in man. Another common assumption is that the effects of alcohol in disease are similar to its effects in health. But this is a totally unproved assumption, and there is, I think, a good deal of evidence that it is not true.

It seems to me, therefore, that there is a real need for exact experimental evidence regarding the action of alcohol in sickness, and it is to this problem that I have addressed myself. I have not sought to show that alcohol does good or that it does harm. I have rather tried to find out *what it does*, what its effect is upon temperature, upon the heart and pulse, upon the rapidity of the respiration, upon the amount of urine, upon the sweat, upon the appearance of the tongue, upon the appetite and upon the cerebral condition of the patient as shown in the amount he sleeps, in the effect of the drug upon delirium, and upon his spirits so far as could be ascertained by talking with him.

I will not deny that I have approached the subject with a marked bias, but I hasten to add that I have done all I could to prevent this bias from influencing my observations. That I have succeeded, at least to some extent, is evidenced, I think, by the fact that my results have not come out at all as I expected and indeed hoped that they would.

In order to counteract so far as possible the bad effects of my prejudices, I have recorded each of my observations on separate slips of paper without allowing myself to refer to the chart in which they were later recorded. As I could not retain in memory the records of the individual patients, and did not allow myself to be reminded of them by looking at the chart, I was thus unable to influence the readings in the direction of my expectations, as I previously found it very tempting to do.

In the study of the effects of alcohol on temperature, appetite, sleep, etc., I have circumvented my bias by getting nurses, who had no idea of what I had in mind, to record the data for me on blanks provided for the purpose.

I have said that there was a dearth of experimental evidence regarding the action of alcohol in diseased persons, but this lack is much more striking in certain directions than in others. Certain points have, I think, been pretty well cleared up, while others are still obscure. Hence it may not be out of place to sum up what may be regarded as relatively settled, in order that the unexplored regions may be made more evident by contrast.

About the food value and the digestive action of alcohol, about its effect on temperature, respiration, the secretions and the susceptibility of the lower animals to infection, there is a good deal that we may consider settled.

On the other hand, there are very few experiments upon its action on the *circulation* of the sick, or upon the protective powers of the human blood against infection.

These two problems, then, confront us:

(1) What effect has alcohol upon the circulation in sick persons?

(2) What is its effect on the power of man's blood to protect his organism against infection?

The first of these two questions I have tried to answer in the present lecture. The second I hope to attack later.

Before presenting the results of my own experiments I will endeavor to summarize what seems to me established as the result of work previous to my own.

We may treat as established the following statements:

I. ALCOHOL AND METABOLISM.

(1) In healthy persons alcohol is capable of replacing satisfactorily the fats and carbohydrates of ordinary food.

(2) It is not yet settled whether or not alcohol can replace the proteids of our customary diet.

(3) The food value of alcohol as a substitute for carbohydrates and fat is perfectly consistent with its toxic properties. It is beyond doubt both a food and a poison.

[1] Read before the Association of American Physicians, May 13, 1903.

II. THE ACTION OF ALCOHOL ON DIGESTION AND ABSORPTION.

(4) While it is in the stomach, alcohol disturbs the digestive processes to a greater or less extent according to its concentration.

After absorption (either from the stomach or from the intestines) alcohol acts upon the stomach through the nervous system, and exerts a favorable influence both on its secretions and on its motility. But the nervous system is soon blunted to its influence, so that more and more is needed to influence digestion.

(5) On the intestinal absorption of food alcohol has no considerable influence so far as is known.

III. ALCOHOL AND DIURESIS.

(6) In healthy persons and in renal or cardiac disease, alcohol has no considerable effect as a diuretic. The free diuresis often seen after beer drinking is due in part to the water ingested and in part to the CO_2 and other non-alcoholic constituents of the beer.

IV. ALCOHOL AND DIAPHORESIS.

(7) The experimental data are not conclusive, and great individual differences exist, but the majority of experiments seem to show that alcohol diminishes sweating in healthy persons.

V. ALCOHOL AND RESPIRATION.

(8) Practically all experiments show that under the influence of alcohol a larger volume of air passes through the lungs. This is especially marked in fatigued persons. There is, however, no increase in the amount of O_2 absorbed or in the amount of CO_2 given off.

The patient is made to do more work in breathing without getting any known benefit from it.

ALCOHOL AND PULSE RATE.

Lichtenfels and Frohlich [1] found first a decrease, later an increase in pulse rate.

Tscheschichin [2] and Ruge [3] noted a very marked rise in pulse.

Zimmerberg [4] could find no variation from normal. Reiss got similar results.

Mertens [5] noted no change, Martins [6] a decrease, Jacobi,[7] Duchek,[8] Hemmeter [9] no increase.

In all the experiments in which subjects have been put into an unchanging environment and conditions, the changes in pulse before and after alcohol sink to a minimum.

Wendelstadt [10] took especial pains that the persons on whom he experimented should remain quiet some time before the beginning of the test and stay in just the same position after swallowing the alcohol. With these precautions the changes in pulse rate were trifling. For a few beats the pulse rate sometimes rose a little, but soon returned to normal. Occasionally there was a slight decrease in rate. The following data may be quoted:

N. K., healthy, fasting, horizontal position for two hours before the experiment.

I.	9.30 A.M.	Pulse 54
	9.50	,, 56
	10.07	Sherry, 300 c.c. (=10℥)
	10.15	Pulse 56
	10.40	,, 56
	11.05	,, 56
II.	Same subject; same conditions.	
	8.55 A.M.	Pulse 60
	9.15	,, 60
	9.30	Brandy, 100 c.c. (3½℥)
	9.40	Pulse 57
	10.00	,, 58
	10.20	,, 58
	10.40	,, 55
	11.00	,, 60

III. Same subject after a hard day's work, and one-half hour in horizontal position.

6.40 P. M.	Pulse 64
6.55	Absolute alcohol ℥ ii diluted
7.05	Pulse 64 (subject drunk)
7.28	,, 64
7.55	,, 68
8.15	,, 64 (less drunk)
8.35	,, 68

To the finger the pulse after alcohol feels fuller and stronger, and the sphygmograph shows a tracing like the "pulsus celer" of aortic regurgitation.

BLOOD PRESSURE AFTER ALCOHOL.

Zimmerberg [11] found after putting alcohol into a cat's stomach a marked fall in blood pressure.

Gutnikow [12] experimented on curarized dogs, into whose stomachs he introduced 250 c.c. of 50% alcohol. The result was a considerable fall in blood pressure, together with a dilatation of the small arteries, capillaries, especially in the territory of the splanchnic.

The dog here used was so small (20 kilos), and the dose so enormous, that no inferences ought to be made from these experiments as to the effect of moderate doses in man.

Weissenfeld [13] reports work done in Binz's laboratory. The experiments were carried out on men with the help of v. Basch's sphygmomanometer. After 2 or 3 oz. of sherry the pulse rose in three cases from 15 to 30 mm. Hg.; in one even as much as 60 mm. Hg.

Passler [14] and Schule,[15] working with Gaertner's tonometer on a healthy man, recorded a fall from 110 to 95 mm. Hg. twenty minutes after sherry and brandy. An hour later the pressure was 115 again.

Rosenfeld [16] worked with dogs, connecting the femoral artery with a mercury manometer. He was careful to avoid the common mistakes of overdosage and over-concentration in the alcoholic solutions used, which were of 10 to 25% strength, and introduced by a tube into the dog's stomach.

The question whether dogs tolerate alcohol better than men seems to be answered in part by the following facts:

(1) It takes the same dose *per kilo* to narcotize an average man or an average dog.

(2) It takes approximately the same dose *per kilo* to kill a man or a dog.

But to make sure that he did not err on the side of too small dosage Rosenfeld increased his doses from the equivalent of ʒ i of whiskey at a time up to the equivalent of ʒ x of whiskey.[17]

The upshot of his 300 or more measurements in 8 dogs was that alcohol has no appreciable effect upon the dog's blood pressure. He used fresh dogs with high blood pressure (152 mm. Hg.), tired dogs with low pressure (82 mm. Hg) and dogs with pressures intermediate.

The result was the same in all cases. Variations in the pressure from hour to hour were no greater than occurred spontaneously, that is, when no alcohol was given.

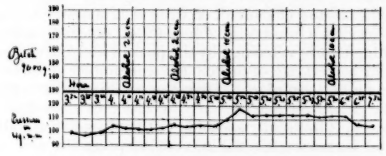

CHART I.— Blood pressures in dog after alcohol. (Rosenfeld.)

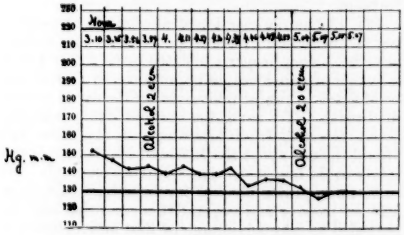

CHART II.— Blood pressures in dogs after alcohol. (Rosenfeld.

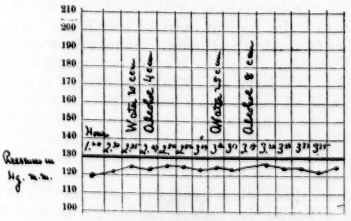

CHART III.— Blood pressure in dog after alcohol.

ALCOHOL AND TEMPERATURE.

In states of profound intoxication, belonging practically to the class of collapse states, there may be a very marked lowering of temperature. Experimentally Rosenfeld produced readings of 88.7 F. in dogs.

Therapeutic doses of alcohol given to sound men seemed to produce a slight lowering, amounting, according to the experiments of Binz's pupils, to about .7° F. In sick people the decrease was about the same. The temperature of the skin is greater than that of the rectum, a fact which seems to indicate that the lowering of the rectal temperature and presumably of that of the internal organs in general, is due to the dilatation of the cutaneous vessels.

Dumouly[18] found that no effect was produced in fever patients by doses of less than 20 gm. of absolute alcohol (= about ʒ iss of whiskey).

ALCOHOL AND THE NEURO-MUSCULAR SYSTEM.

The most recent and careful researches on this much-disputed point seem to show that in fresh healthy men the power of voluntary muscular movement is increased about 7% for the first one-half hour, after which there is decrease to a point about 5% below the normal.

By diminishing the sense of fatigue, alcohol undoubtedly enables men to push themselves for a short time beyond the limit which nature would otherwise have imposed upon them through fatigue.

ALCOHOL AND THE SUSCEPTIBILITY TO INFECTION.

Latinen found a decrease in the number of leucocytes in cases of pneumonia during alcoholic medication, and Massart and Bordet observed a negative chemo-tactic effect upon leucocyte even with very dilute solutions of alcohol.

That it increases in animals the susceptibility to infection and diminishes the animal's power of resistance has been shown so many times and in so many ways that it is not necessary to go over the evidence in detail.

In man something more or less akin to experimental evidence in this matter is furnished by the well-established fact that alcoholics are predisposed to infectious diseases, and have them in a very virulent form.

More direct and important evidence is furnished by researches designed to investigate the antitoxic power of the blood in health and in disease with and without alcohol.

Mircoli[19] compared the antitoxic power of normal human blood with that of alcoholics by testing the power of each to neutralize Maragliano's tuberculin. The blood of normal men was found to neutralize large doses of this toxin; for example, 10 cc. of this tuberculin is a fatal dose for animals of 1 kilo weight. But this animal can be protected against this dose by the injection of 2 to 3 cc. of normal human serum. The serum of chronic invalids, on the other hand, does not possess this power.

But the serum of drunkards was found to be much more strongly antitoxic than that of normal men. In one case $\frac{1}{10}$ of a cc. of drunkard's serum was sufficient to protect a kilo animal against 10 cc. of tuberculin. From these facts Mircoli concludes that alcohol is a most valuable remedy for tuberculosis, forgetting that tuberculin and tuberculosis

[17] Two cc. of alcohol at a dose for a dog of 8 kilos, corresponding to a little over ʒ i of whiskey for an adult.

[18] Paris Thesis, 1880.

[19] La Clinica Medica Italiana, March, 1900, p. 133.

are by no means the same, and that alcoholic cirrhosis and tuberculosis of the lungs or peritoneum are very frequently associated.

Nevertheless, Mircoli's results are of great interest both in themselves and as an indication of the direction in which future research should be turned.

More recently Abbott and Bergey [20] have undertaken a study of the blood reactions of normal and alcoholized rabbits by Ehrlich's methods. Their conclusions are:

(1) The daily administration of alcohol per os to rabbits reduces the amount of hemolytic complement in their blood.

(2) The diminished reactivating power of the blood of alcoholized rabbits is not due to the presence of small amounts of alcohol as such in the blood.

(3) Alcohol not only reduces the amount of complement in the rabbit's blood, but may cause at the same time a reduction in the number of free specific receptors in the blood of a rabbit artificially immunized against an alien blood.

(4) The diminished complement-content of the blood of alcoholized rabbits renders the animal more susceptible to the toxic action of an alien blood.

THE TOLERANCE OF FEBRILE PATIENTS FOR ALCOHOL.

It must have forced itself upon the notice of any one who has watched the effects of alcohol in fever cases that such patients will stand an extraordinary amount of the drug without any signs of intoxication.

For example, I recently watched a patient with typhoid in the service of Dr. F. C. Shattuck, who took for nearly a fortnight 2 oz. of whiskey every hour, day and night, that is, three pints of whiskey every twenty-four hours, without any sign of intoxication. In the same service a young girl also suffering from typhoid took 60 oz. of champagne, nearly two quarts, every day for three weeks without any of the ordinary evidences of intoxication.

This certainly proves that alcohol acts differently in disease and in health, and makes it obvious that the results of experiments with alcohol on healthy men should not be supposed to prove what its effects in sickness may be.

But because alcohol acts *differently* in disease, are we obliged to suppose that it acts *more beneficially* than in health?

That we do not smell it in the breath of typhoid fever patients, despite a dosage which would make a well person reek with it, does not point to any considerable difference in the amount burned up in the body, for even in the intoxicated states produced by alcohol in healthy persons, 98% of the alcohol is burned in the body. The alcoholic odor in the breath does not prove that any considerable portion of the alcohol is being excreted through the lungs.

Alcohol given to dogs with sugar does not make them nearly as drunk as when it is given without sugar, [21] but its harmful effects are no less marked.

That sick persons are not intoxicated even by enormous doses of alcohol gives us no evidence whatever that it is doing good, nor on the other hand is it a reason for believing that it does harm. It is an interesting but a wholly neutral fact so far as the therapeutic value of alcohol is concerned, and is important chiefly as a warning to those who tend to argue directly from the known effects of the drug in health to its supposed effects in disease.

THE PSYCHIC EFFECTS OF GIVING ALCOHOL.

(1) On the mind of the physician and of the patient's family or friends.

(2) On the mind of the patient himself.

(1) The virtues of alcohol as a stimulant have been so firmly established in the minds of the laity that both the patient and his friends are apt to be comforted by the knowledge that it is being given. It does not sound exactly like a drug, its taste is generally not disliked, and the cheering impression that something is being done, and done pretty frequently, is diffused among those who are caring for the patient, and may reach the mind of the patient himself.

By a sort of auto-suggestion, a similar impression is sometimes produced upon the physician as well. It is very hard to sit still and do nothing for the patient, and when we have no very reasonable belief in the efficacy of a drug it is a relief to the physician's mind to give *something*, especially something that is welcomed by the patient and his friends, and something of which the community generally has a high opinion. Then the soothing effect upon the patient, which the narcotic action of alcohol produces, is indirectly soothing to the physician as well, and increases his willingness to prescribe and to continue the so-called "stimulant." In short, alcohol makes physician, patient and friends more comfortable.

(2) The narcotic action of alcohol, its tranquillizing and benumbing effects upon the nervous system, have been very properly insisted on as a therapeutic influence of considerable importance by Cushny and by Meltzer in recent addresses on the use of alcohol in disease. To save the patient from worrying about himself, from broodings on the cause and apprehensions about the future of his disease, is certainly to do him a service. But we cannot, at the same time, praise alcohol for bringing the patient into so passive and vegetative a condition and expect also to take advantage of that active, fighting, determination to get well which many physicians suppose to have a real effect in combating disease. Either the tranquillity or the actively resistant will-power of the patient must be sacrificed. Whether either factor has any genuine influence on the course and outcome of disease is entirely a matter of guesswork. We have no definite knowledge in the matter, and all that I mean here to point out is, that if we are to maintain that the narcotic effect of alcohol is beneficial, we must give up the idea that the patient's will-power is an important factor in his recovery.

But although it is generally assumed that alcohol has a benumbing effect, and so a tranquillizing effect upon the patient, it has not been my experience that any such effect is always or even usually to be observed. That very striking *neutrality* of alcohol, which has been my chief lesson throughout all the other observations which I have made on its action, has impressed me and surprised me afresh in studying its psychic effect. Only in four out of the sixty-nine cases in which I have watched for

[20] Univ. of Penn. Med. Bull., Aug.-Sept., 1902.
[21] Rosenfeld: Loc. cit., p. 162.

the tranquillizing effect of alcohol has any such effect been noticeable. In the vast majority of patients as I talked with them, several times each day during a period of about six weeks, no change whatever in the prevailing mood could be determined. The down-hearted patients were not notably more or less down-hearted, the cheerful ones were neither more nor less cheerful. One patient in especial, in whom the dose of sixty ounces of champagne per twenty-four hours was suddenly cut off, showed not the slightest psychical change that I could detect.

A few of the typhoid patients seemed to sleep a larger part of the day during the time when alcohol was given them, but it was difficult to be sure that this change would not have taken place spontaneously. In one patient who became more sleepy just after the alcohol was given him, the sleepiness continued just the same for the next ten days after the alcohol was withdrawn, in fact until the temperature became normal.

Very likely finer psychical tests, such as Kraepelin employed in his studies on typesetters, would have shown that, in disease as in health, the associations and reactions necessary for the more delicate psycho-motor processes are slowed by the action of the drug; but that any constant effect was produced on the temper, mood and spirits of the patient I could see no reason to believe.

MEASUREMENTS OF BLOOD PRESSURE.

From this résumé will be seen that no considerable amount of work on the estimation of blood pressure in human beings during the administration of absolute alcohol has so far been done. Rosenfeld's observations are, it seems to me, conclusive, so far as concerns the effect of the drug upon dogs, but we cannot immediately reason from its effect in healthy or in tired dogs to its effect in sick men. Accordingly, I have undertaken a series of measurements of the blood pressure before, during and after the administration of alcohol in patients for the most part sick with typhoid fever in the medical wards of the Massachusetts General Hospital. I am epecially indebted for the opportunity to carry out these researches to the kindness of Drs. F. C. Shattuck and R. H. Fitz. My method of work has been the following:

Two instruments have been used: the Riva-Rocci machine for the estimation of the maximum or systolic pressure, and Oliver's hemodynamometer for the estimation of minimum or diastolic pressure. The working of these instruments may be explained in a few words.

The Riva-Rocci apparatus consists of a dilatable rubber armlet about three inches wide, covered with tough canvas as a support to the rubber, and arranged by means of a series of hooks and eyes so that it can be tightly fitted to arms of any size. By means of a V-tube air is blown simultaneously into this armlet and into the bulb of a mercury manometer. For inflation an ordinary cautery bulb was used.

To use the instrument we attach the armlet snugly around the patient's upper arm about two inches above the bend of the elbow, and force air into it until the radial pulse disappears. When the radial pulse is no longer felt, we note the point to which the mercury column has been forced up and record the reading in millimeters. The instrument appears to be very accurate in the sense that different observers after an equal amount of practice read practically the same independently, and that successive readings by the same observer in the same patient do not vary more than 3 or 4 mm. of mercury. It is very easy to use, and requires very little practice. It is not at all painful to the patient, as I have ascertained by many experiments upon my own arm, and no patient has complained of it in any way, although in some cases more than a dozen readings were taken in the course of a day. No bad effects upon the arm of the patient have occurred, although the cases selected were mostly typhoid, in which the thrombosis is well known to be favored. Any errors that there may be in the instrument may be disregarded in a series of comparative observations upon the same patient by the same observer, since the amount of error is presumably the same in all the measurements.

Oliver's hemodynamometer is a more difficult instrument to use. It consists essentially of a hollow rubber pad filled with glycerine and water which is put over the radial artery and through which the pulsations of the artery are transmitted to a rigid rod and thence through a ratchet and pinion adjustment to a needle moving upon a clock-face dial. By exerting pressure with the instrument through the pad upon the radial artery the needle is made to revolve and, by suitable pressure, the pulse may be obliterated. If, then, we relax the pressure upon the artery until a faint pulsation is permitted, this pulsation is represented by slight oscillations of the needle. As we relax the pressure gradually more and more, the needle upon the face of the dial has a double motion. It moves backwards towards the starting point (zero) and it also oscillates back and forth during its course. These oscillations gradually increase up to a maximum as we relax the pressure, after which if we relax it still more, the oscillations begin to diminish and gradually disappear as the needle approaches the zero of the scale. The maximum oscillations in normal persons occur between the points marked 100 and 130 on the scale. But the pressure within the fluid pad of the instrument is the same as that within the artery when its maximum oscillation is reached, and this corresponds, as Howell has shown, to the minimum or diastolic pressure. The fluid pad obviates the difficulties of applying the instrument over the uneven surface of the wrist. The soft and elastic surface of the pad adjusts itself among the structures of the wrist, and gets into contact with the artery at some point, provided the artery is palpable at all. The chief difficulties in using the instrument are (1) to hold it steady without increasing or decreasing the amount of pressure used upon the artery, and (2) to record accurately the position of the swiftly-moving needle. With well sustained pulses it is very easy to see just where the needle starts and where it ends in each of its excursions, but in the bounding pulses of febrile patients this is often very difficult. With a moderate amount of practice, however, different observers do not vary more than five points in the

scale in their readings. My instrument reads about twenty-five Hg. too high. Accordingly I subtract twenty-five from each of its readings. This prevents their possessing absolute values, but leaves unchanged the *variations* from hour to hour, which is all that I attempt here to record (see charts).

With these two instruments we have made 1,169 measurements in 58 individuals. We began by taking observations every half hour to determine the amount of range of variation at short intervals. Later we took the measurements every hour and every two hours and finally every four hours, as the variations in the smaller periods of time were insignificant, or were excited from moment to moment by occurrences, the mark of which would be as likely to escape detection in half hourly as in four hourly measurements. Thus a cry or groan from another patient in the ward, the approach of dinner or the answering of a question needing some thought would send the blood pressure up a number of points, the rise lasting only a few minutes.

We began our four hourly measurements on febrile patients recumbent in bed and upon unvarying diet. After two or three records with each instrument the patient was given either half an ounce of whiskey or an equivalent amount of absolute alcohol properly diluted and flavored. This dose was repeated every four hours for the first twenty-four hours and then doubled and continued for twenty-four hours more. After that it was, in the majority of cases, omitted, although in a few it was continued several days more in order to ascertain whether any further effect was produced after the first forty-eight hours. After stopping the alcohol we continued our readings for at least twenty-four hours and often longer.

Among the cases studied were 25 of typhoid fever, 2 of pneumonia, 2 of chronic valvular heart disease, 2 of malignant endocarditis, 2 of gonorrheal arthritis and 1 each of the following: pleuritic effusion, Addison's disease, cirrhosis of the liver, thrombosis of a leg vein, tuberculous peritonitis, myelitis and phthisis.

Summing up in a few words the total result of these 1,105 measurements: They indicate that in cases of the type studied, alcohol has no considerable effect either upon the heart's action or upon the tension of the peripheral vessels that can be measured by the instruments employed. I must confess that this result was a great surprise to me. Some effect, either for good or evil, some cardiac stimulation or some vascular relaxation, I had certainly expected to see, but the result, like all those obtained in my investigations of the effects of alcohol on other functions of the body, was practically *nil*.

The following charts and tables give further details of the work.

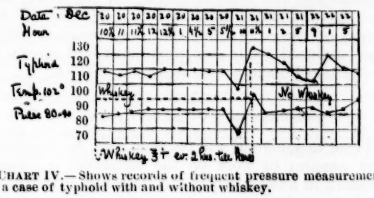

CHART IV.—Shows records of frequent pressure measurements in a case of typhoid with and without whiskey.

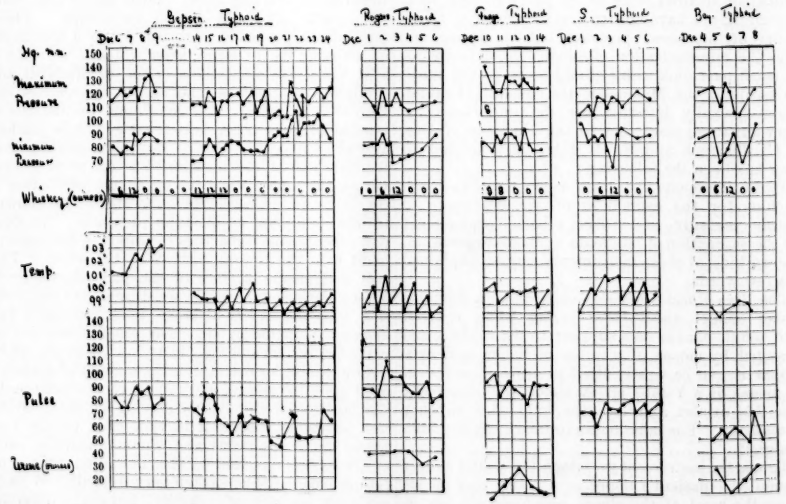

CHART V.—Variations in blood pressure measured every four or eight hours in cases of typhoid, before, during and after whiskey.

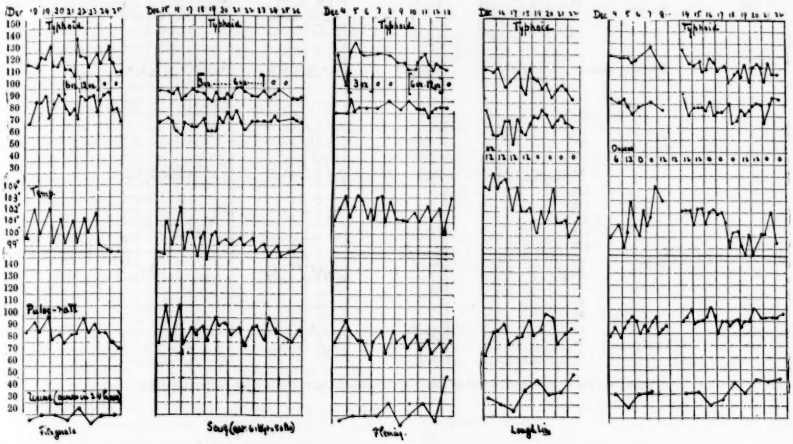

CHART VI.— Same as Chart V.

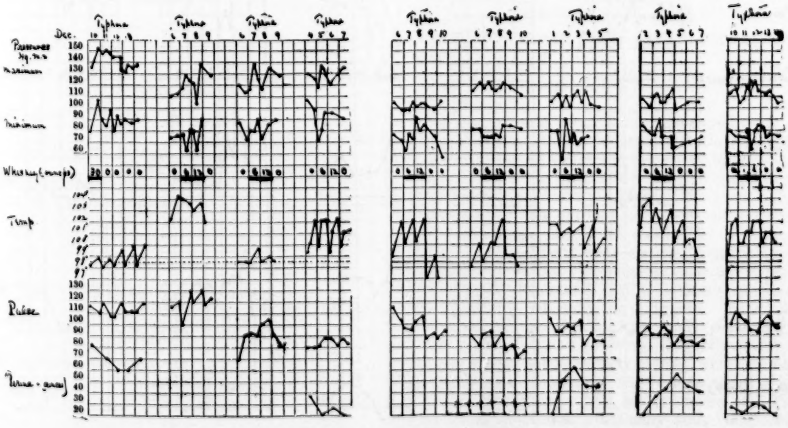

CHART VII.— Same as Charts V and VI.

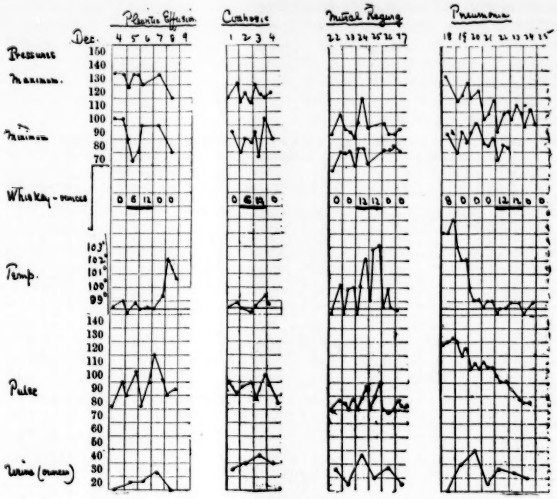

CHART VIII.— Blood pressure in various diseases before, during and after whiskey.

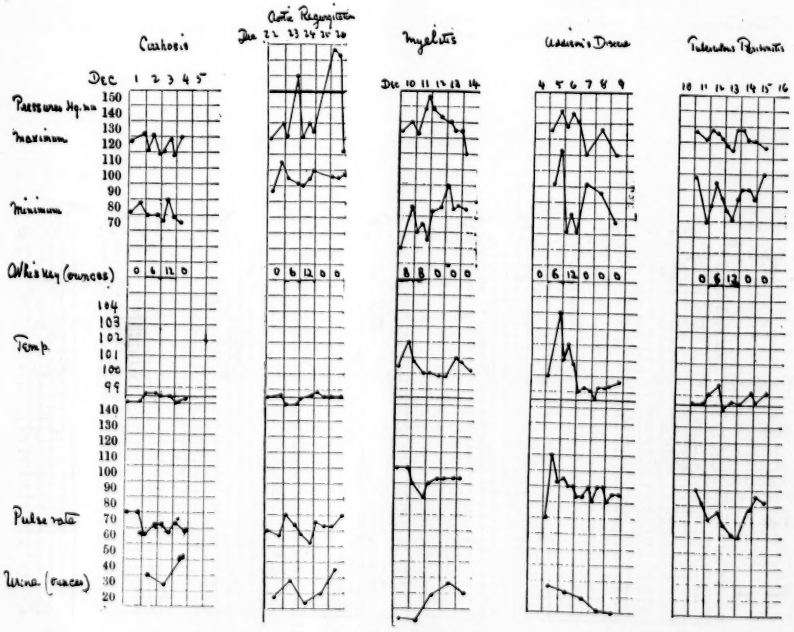

CHART IX.— Same as Chart VIII.

SUMMARY AND CONCLUSIONS.

(1) In 41 patients, mostly cases of typhoid fever, 1,105 measurements of the blood pressure were made before, during and after the administration of alcohol in therapeutic doses. Neither the maximum nor the minimum blood pressure showed any variations that could reasonably be referred to the action of the alcohol. So far as was determined by the methods and in the cases used in this research, the action of alcohol upon the circulation was *nil*.

(2) The same neutrality and apparent inertness of therapeutic doses of alcohol in relation to the temperature, pulse rate, respiration rate, appetite, sleep, delirium and secretions (renal and cutaneous) of 309 patients suffering from a great variety of diseases was the total impression derived from 2,160 observations in these cases.

(3) These observations are not interpreted as proving that alcohol is useless or useful in disease. As a narcotic and vaso-dilator it may have an important place in therapeutics.

(4) More important probably than any of the questions investigated so far is the problem of the effect of alcohol upon the power of the sick man's blood to protect him against infection and other harmful influences. The studies of Abbott and of Mircoli have begun to clear a path in this direction, and we have a certain amount of evidence relative to a similar problem in the lower animals. But as the results of studies regarding the action of alcohol upon animals or upon healthy men cannot be used as evidence of its action in sick men, there is a good field for experimental work in this direction along the lines of Ehrlich's newer methods.

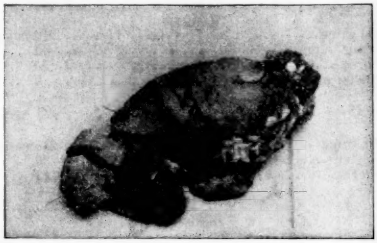
Clinical Department.

CLINICAL MEETING OF THE STAFF OF THE MASSACHUSETTS GENERAL HOSPITAL, FEB. 20, 1903.

(Concluded from No. 3, page 73.)

DR. E. A. CODMAN presented the following three cases:

CASE I. *Traumatic rupture of kidney; nephrectomy; recovery.*



This patient was brought to the accident room on Aug. 28, 1902. He is a brakeman on the N. Y., N. H. & H. R. R., and was struck in the side by a wooden awning while climbing a ladder on a moving freight car about an hour before entrance. He managed to climb on top of the car and lay down and was soon afterward brought here in fair condition. The house officer in the accident room watched him for about an hour, and as the symptoms of internal hemorrhage rapidly increased and a catheter specimen showed clear blood, sent for a surgeon. Since the patient was in great pain, extremely pallid, rigid in the right flank and growing distinctly worse, I thought it wise to explore the kidney, which I found in fragments. I ligated the vessels which were attached to the lower half and removed it. The upper half, which was practically free, being only held by a few shreds of capsule, was removed

separately. The hemorrhage was very severe throughout the operation, which only took a few minutes.

He made an uneventful recovery.

These fragments which have been hardened in formalin give a poor idea of the amount of laceration, as they were molded together before placing them in the formalin.

The patient has been perfectly well since leaving the hospital. The scar in the right flank shows the region of the incision.

Although in this case nephrectomy was clearly indicated, I want to say that I do not believe in nephrectomy for every case of traumatic rupture of the kidney, for undoubtedly most cases get well without interference. Exploration of the kidney was indicated by the rapid increase of the symptoms of internal hemorrhage and the filling of the bladder with clear blood. When the incision exposed the kidney the hemorrhage was so great that nephrectomy was the only course, as the bleeding could not have been stopped by packing.

CASE II. *Osteo-chondroma of posterior surface of pubes; excision; recovery; no recurrence in a year and a half.*

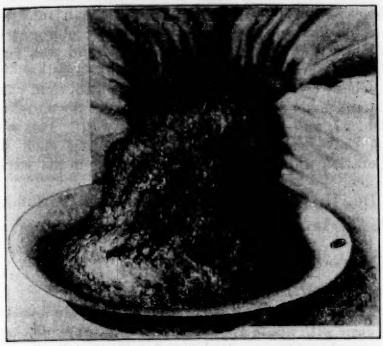
This patient was operated on July 1, 1901. His previous history was unimportant. He was a well-developed man of twenty-seven in first-rate condition. Eight years before he had first noticed a tumor in the suprapubic region. It had grown steadily, and at the time of the operation was about the size of an orange and of an irregular lobulated shape. It arose from the posterior and upper surface of the left pubic bone and pressed the bladder backwards. One lobe had grown down the femoral canal and about the great vessels, which lay in a sort of tunnel through the growth. The cord of the left testicle also lay in a sort of tunnel in the mass. At the base the tumor was of cancellated bone, though many of the lobules were hyaline cartilage with myxomatous degeneration at their centers.

The operation is of interest on account of the anatomical relations of the structures involved. I made a crescentic incision from the left anterior-superior spine two thirds of the way to the right and a vertical incision over the femoral artery. The testicle and cord were removed from the scrotum and canal, and hung in a wet towel over the patient's left side. The insertions of the rectus and the oblique muscles, Poupart's ligament, and all the adductors of the thigh were cut entirely free from their pubic attachments and reflected. By pushing aside the peritoneum this gave easy access to the tumor, the bladder and the iliac and femoral vessels. The growth, with practically the whole left pubic bone and part of the right, was chiselled away, leaving only an outline of normal bone above the obturator foramen. The large gap thus made was then closed by returning the attachments of the muscles in their natural order, sewing the adductors of the thigh to the rectus and abdominal muscles as well as what remained of the pubic bone. A new canal was made for the cord and the testicle returned to its former pocket in the scrotum.

He made a good recovery and has remained well since. There is a slight bulging in the region of the scar, but no true hernia.

CASE III. *Intussusception in a man of twenty-four; resection of the intestine; recovery.*

This patient was brought to the hospital on Sept. 26, 1902. His history, signs and symptoms were typical of a severe case of appendicitis with a large abscess. Examination showed a large "cake" in the right iliac fossa. His bowels were said to have moved twice and there was no blood in the stools. The only symptom which I can recall that was against appendicitis was the persistent vomiting since his first attack of pain three days before. In appendicitis the vomiting is apt to be intermittent.



Supposing the mass in the right iliac region to be an abscess, I opened the abdomen, using Dr. Harrington's modification of the McBurney incision. The mass proved to be intussusception of the ileum almost reaching the ileo-cecal valve. It was easily resected and a simple end-to-end suture done. The patient was under ether an hour and ten minutes and barely recovered. This is the specimen. It consists of about three feet of intestine. The region where the upper segment enters is so tightly twisted that reduction was obviously impossible even after resection. The pent-up blood clot between the walls offers an explanation of the fact that the stools were not bloody, that is, the obstruction was complete.

The patient as you see is well, and thanks to the modified McBurney incision his abdominal wall is as good as ever. This is the first case of successful resection for intussusception at this hospital and one of the few recorded cases in adults, I think the oldest in point of age.

HYDATID MOLE.

DR. J. COLLINS WARREN showed a water-color of a case of Cæsarean section for hydatid mole. The drawing was made by Mr. Aitken, and showed very perfectly the gelatinous structure of the mole and the method of operation. The patient, an Assyrian, was twenty-two years of age, was regular up to last September, when from the 20th on flowed profusely for ten days. Since then, a tumor has gradually developed with pain on right side of abdomen. On entrance Nov. 28, 1902, a tumor was found reaching to the umbilicus, soft and somewhat fluctuating. Vaginal examination showed a soft and patulous os. The patient was examined by Dr. W. L. Richardson, who decided there was no pregnancy and advised exploratory

incision. This was done Dec. 2. On opening the abdomen the uterus was seen symmetrically enlarged and extending to the umbilicus. There were no signs of fetal contents and the organ fluc-

tuated distinctly — the uterus being carefully walled off. An incision was made in the median line and the contents emptied into a basin. The wound in the uterus was stitched with two layers of catgut sutures and the wound in the abdominal wall closed with interrupted sutures. The patient made a good recovery, but the uterus was not fully involuted at the time of leaving hospital on Dec. 26. A month later the patient returned to the hospital for profuse flowing, for which the uterus was curetted. She was discharged from the hospital Feb. 3, "much relieved," but is still kept under observation, as flowing threatens to recur.

CURE OF UMBILICAL HERNIA.

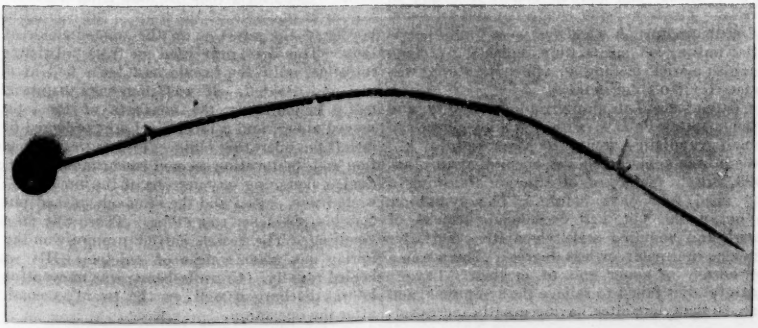
DR. WARREN reported two cases of umbilical hernia in stout women in whom the operation for medical cure was combined with the excision of the adipose tissue of the abdominal wall. The cases will be reported at length in a separate article.

DOUBLE HALLUX VALGUS.

The patient, a young man aged eighteen, presented himself at the hospital with enlargement of big toe joints of both feet. Had worked up to two days before entrance. His occupation was that of a clerk. The right foot had troubled him specially for a month and the left toe joint became inflamed two weeks ago, and at time of entrance there was a discharging sinus over the joint. There was also a slight ulceration of the skin over the other joint. Both joints were much swollen and the skin reddened.

After a few days of rest in bed an operation was performed, which consisted in opening the joints by a longitudinal incision about one inch in length, removing the ulcerated skin at the same time. The head of the metatarsal bone was removed in each case and the wound closed by deep catgut sutures through the synovial membrane and silkworm gut sutures through the skin. The feet were then placed in a posterior wire splint.

A slight discharge of synovial fluid continued for about three weeks and then ceased.



When exhibited at the clinical meeting one month after the operation the patient expressed great relief and the wounds appeared to be healed with the exception of a pinpoint scab on one toe. The patient walked about without difficulty and was ready to resume work. The deformity of the inner border of the feet had been entirely removed by the operation.

GASTROTOMY FOR FOREIGN BODY.

DR. WARREN showed a hat-pin five inches long removed from the pyloric end of the stomach.

The patient, a married woman forty-five years of age, had entered the hospital with the history of having swallowed the pin twenty-four hours before. She was suffering from melancholia. Patient stated that she was obliged to bend the pin, as shown in photograph, before being able to swallow it head first.

The next day she complained of a pricking feeling in the epigastrium, and confessed her act. There was a pin missing from her room. Beyond the slight pain there were no symptoms. An x-ray plate examination was negative in its results. Dr. Warren passed an ivory-tipped probang down the esophagus, but nothing was found there. Rectal examination was negative. A fluoroscopic examination showed a shadow about four inches long, which could be seen very distinctly at times, when

patient was standing. With patient lying on her side this shadow could not be seen. Mr. Dodd concluded that the pin was probably free in the stomach and when the patient was turned on her side the pin fell toward the median line and escaped from view behind the liver.

After twenty-four hours' observation it was decided to make an exploratory incision—although the x-ray plates had not given a positive result. There were no new symptoms. A four-inch median incision was made between ensiform cartilage and umbilicus, exposing anterior wall of stomach. The point of the pin was found protruding from the pyloric end of stomach and piercing the outer edge of the lesser lobe of the liver. An inch incision was made through the anterior wall of stomach, and the finger was introduced, but the pin could not be felt. It was then apparent that the head of the pin was in the duodenum and the greater portion of the shaft was lying between the mucous membrane and muscular wall of the stomach, having been pushed upwards by the peristaltic action of the bowel in its efforts to pass the pin around the curve of the duodenum.

The tip of the pin was now seized, it having freed itself from the liver, and was drawn upwards until the head pressed against the peritoneal covering of the stomach. A small incision allowed it to escape. The two incisions in the stomach were sewed up and the abdominal incision closed, a small wick being left in at one point. The wick was removed on the following day. The patient was fed by nutriment enemata for about a week, and left the hospital two weeks later, having entirely recovered from the operation, although her mental condition remained the same.

INTESTINAL OBSTRUCTION FOLLOWING OPERATION FOR APPENDICITIS.

[In the discussion of Dr. Beach's case of obstruction following an operation for appendicitis, DR. WARREN reported the following case, which had just been discharged "well" from the hospital.]

J. M., barber, twenty-eight years of age, was operated upon June 14, 1902, for an appendix abscess, accompanying gangrene and perforation of the tip of the appendix. Numerous colonies of bacilli of the colon group were found in the culture taken at the time, from cloudy fluid filling pelvis and in region of appendix. Culture taken from near middle line showed mixed infection in coverslip. The bowel was congested and adhesion found near cecum. A wick was passed into pelvis and the walling off wicks were replaced by clean wicks, also a wick leading to appendix stump was introduced. No stitches taken.

The patient made an uninterrupted recovery, and left the hospital Feb. 4, with "wound closed all but small granulating area at its lower end."

Patient was admitted to the hospital again Jan. 2, 1903, with a history of obstruction following a hearty meal four days before. The symptoms were not acute, but had occasional attacks of hiccough and vomiting and tympanitis, the latter continuous in greater or less degree. There was a slight hernia at upper end of cicatrix. Lavage and careful diet failed to relieve the symptoms, and on Jan. 29 the tympanites having greatly increased, Dr. Warren opened the abdomen through a six-inch incision, parallel to line of old scar on either side. A band was found extending from the peripheral surface of a coil of small intestine to the old cicatricial area in the right iliac fossa. Beneath this band another coil of small intestine was caught and its lumen practically obliterated. While withdrawing this loop, the band was ruptured. The wound was brought together by stitches throughout its entire length, and the patient made an uneventful recovery. Seen to-day, Feb. 24, and pronounced entirely well This was the only case of obstruction following such an operation which Dr. Warren had had in his experience.

DR. H. H. A. BEACH next showed the following cases:

INTESTINAL OBSTRUCTION FROM A TWIST AND A TIGHTLY CONSTRICTING BAND.

The patient, a boy of sixteen, entered the hospital in June with acute appendicitis. The appendix was removed and the cavity drained. He was discharged well, but re-entered in July, for abcess in the wound, which was opened and drained. Rapid healing followed. Since leaving the hospital he has enjoyed good health, with the exception of occasional attacks of indigestion. Three days ago he had what was called an acute attack, with general abdominal pain, gradually increasing in severity, becoming sharp and paroxysmal. He vomited first food, later, greenish material, and on the morning of re-entrance to the hospital a dark brown fluid. The bowels had not moved from the beginning of the attack, though cathartics had been freely used. I found the abdomen distended and tympanitic. There was no muscular spasm or tenderness. Shifting dullness in the flanks. No induration could be detected. The legs were flexed, and there was considerable pain. Pulse 120, regular, of fair volume and tension. Bulging of anterior rectal wall, no ballooning. Heart and lungs normal. A high enema was given without a result.

Laparotomy five inches to the right of the median line at the outer edge of the rectus muscle — two pints of clear serum evacuated. A loop of small intestine, much distended and reddened, was found on the right side, the loop formed by a complete twist of the gut, and held in this position by a firm band, extending across the loop from the intestinal border of one side of the loop to the corresponding border of the intestine on the opposite side of the loop. This band prevented me from untwisting the intestine, until the former had been tied at either end and divided. It was then easy to untwist the coil. Immediately the contents of the intestine moved along, and a fecal discharge occurred before he left the operating table. The degree of constriction and its duration seemed remarkable in not producing sloughing or gangrene of the intestine. The wound was closed and the stomach washed out before his recovery from ether. There was no more vomiting. The bowels moved promptly on the following day after a dose of calomel. His wound healed rapidly. Convalescence was uneventful and he was discharged well, on the twenty-second day after the operation.

NEEDLE IN KNEE-JOINT.

The x-ray plate shows about half of a needle imbedded in the inner condyle of the femur of a young child. A few hours before entering the hospital, he had, by kneeling upon some cloth holding the needle, driven it directly into the bone and broken it, the part holding the eye being left outside the joint. Through a small incision the joint was opened and a black spot corresponding to the fractured end of the needle found flush with the cartilaginous surface. A disk of cartilage with the needle insertion as a center was removed, when the needle projected sufficiently for the forceps to grasp and extract it from the bone. The joint was closed and recovery prompt.

APPENDECTOMY INCIDENTAL TO SALPINGECTOMY.

The specimen is presented to illustrate the attachment of the appendix to the Fallopian tube of the right side by inflammatory adhesion — and the probability in such cases of more serious consequences from appendix complications in delayed operations than in those where the tubes alone are involved.

ABDOMINAL INJURIES WITHOUT EXTERNAL SIGNS.

The lack of general interest in these injuries, which are commonly classified under the head of internal injuries, though they are much more frequent than penetrating wounds, suggested the report of the following case. Their expectant treatment involves great responsibilities, for if hemorrhage or extravasation occur, early infection or exhaustion may soon place the patient beyond the reach of surgical interference. In the first case occurring in my service there were multiple fissures of the liver, kidneys and spleen, with extensive sub-peritoneal hemorrhage; the injury caused by a fall of sixty feet. In the second there was a longitudinal tear of two inches in the small intestine, caused by the kick of a horse. In Dr. Mixter's case there were no external signs, but the small intestine was torn apart and the two ends separated three inches.

In Dr. Greenough's case there was no symptom but muscular retraction, and the small intestine had been torn open toward the mesentery.

The patient presented had a fall of eighteen feet, forty-eight hours before reaching the hospital. A ladder upon which he was standing suddenly broke. He could not tell how he struck the ground. Two lower ribs on the right side were fractured in the anterior axillary line. He had severe abdominal pain not localized on the following night, and vomited once. There had been no movement of the bowels for two days, though enemas and cathartics had been freely used. Pulse 84. Temperature 99. White blood count 29,000 at time of admittance. The abdomen was much distended, tympanitic, painful and tender throughout. No spasm except in gall-bladder region near broken ribs. No dullness in flanks. Rectal examination negative. Urine normal. Three hours later, about the same condition, with increasing dullness of flanks. Result negative from high injection.

From the pain, tenderness, distention, obstruction, it seemed judicious to explore the peritoneal cavity for possible visceral injury. Laparotomy of six inches in the median line. Intestines much distended and injected, no free fluid, collapsed bowel blood or fecal extravasation. The wound was carefully closed. A large fecal evacuation occurred on the following morning, and much relief to all of his symptoms followed the examination. His recovery and convalescence were uneventful. Whether the injury had the effect of displacing the intestines in such a way as to produce a kink, obstructive in character, I do not know, but no other explanation of the apparent relief from interference seems more reasonable.

THEOCIN AS A DIURETIC.

DR. R. H. FITZ presented some charts showing the results of the use of theocin. In a case of adherent pericardium, with ascites, the flow of urine was at once increased from 15 to 90 oz. when 5 gr. of theocin were given three times daily. In a case of arterio-sclerotic myocarditis 5 gr. doses of theocin increased the secretion of urine from 25 to 90 oz. But little effect followed its use in a cardio-renal patient, while in one with chronic diffuse nephritis 5 gr. doses, three times daily, increased the flow from 20 to 90 oz.

IDIOPATHIC DILATATION OF THE COLON. PHANTOM TUMOR.

The patient, a neurasthenic and hysterical single woman, twenty-four years old, had been operated upon on account of a floating kidney, but without relief. When lying on her back there was nothing abnormal in the appearance of the moderately distended abdomen. As the head and shoulders were raised the contraction of the recti muscles caused an asymmetrical, tympanitic tumor to project in the lower abdomen, bulging especially in the right iliac fossa. The oblique muscles were flaccid. The deformity also was apparent when the patient stood.

OBLITERATION OF THE INFERIOR VENA CAVA.

The specimen from the patient with dilated veins from obstruction of the inferior vena cava shown at a previous meeting had been prepared by DR. JOHN WARREN and was exhibited. Just below the entrance of the hepatic vein there was a complete obliteration of the inferior cava about a half inch long. From this point to the pelvic brim the vein was dilated somewhat and filled with a laminated, in part decolorized thrombus.

The femoral vein for some two inches below Poupart's ligament was transformed into fibrous tissue and could not be distinctly isolated. The collateral circulation was afforded by distention of the spermatic veins and of the superficial veins of the abdominal wall, but especially by the greatly distended azygos veins. The upper portion of the right azygos vein was nearly as large as the forefinger.

CASE OF PAGET'S DISEASE,

from Dr. F. C. Shattuck's wards, was shown by DR. RICHARD C. CABOT. This patient knew of his trouble simply from the bowing of the legs. It has been going on for three years. The x-ray shows that not only are the tibia and femur affected, but

the smaller bones of the foot and the bones of the arm and the clavicle, of which he was not aware. I have here some x-ray plates which show the thickening of some parts, and decalcification of some others. In the hospital, when he is sitting down or lying down, he is very comfortable, but when he tries to stand he gets very tired.

This disease used to be called very rare. Up to 1901 only seven cases had been reported in America, but since Dr. E. A. Locke and Dr. Joel Goldthwait have looked it up, a number of cases have come to light, so that Dr. Locke, who is making a careful study of the disease, has notes of twenty-one cases living in and about Boston.

The next case is one of gastric ulcer in a child of eight years. It was accompanied by fever, at the times of bleeding, as you will notice by this chart. We have looked over the hospital records, and find that out of 487 cases of gastric ulcer there have been 4 cases under fifteen years; 14, twelve; 10, eight, respectively, this child being eight years of age. Before the child came into the house she lost about a quart of blood from the mouth. Since coming in here has had one or two small hemorrhages. The points of interest are, first, that the girl is so young; second, that hemorrhage each time is accompanied by fever, and that it was some days before it came down to normal. Of course we do not know that it is gastric ulcer; but there were tarry stools and vomiting of blood, and we have no other explanation as yet.

NITRIC ACID IN THE STOMACH.

This case of Dr. S. J. Mixter's was shown by DR. BENNER.

This case, which Dr. Mixter wishes reported here to-night, is that of a man brought to the accident room last August in a state of collapse. He had swallowed about two tablespoonfuls of nitric acid, mistaking it for gin. After two weeks he was discharged from the hospital much relieved. He came back about three weeks after his discharge very much emaciated. He was able to swallow, but unable to retain anything. Dr. Mixter operated on him about seven weeks after and found the pylorus completely obstructed. He did a gastro-enterostomy. The man after the operation weighed 100 pounds. He is now able to eat anything, and weighs 175 pounds.

CLINICAL MEETING, FEB. 20, 1903.

(1) *J. J. Putnam:* Insular Sclerosis, 2 cases; Charcot's Joint, 2 cases. (2) *A. K. Stone:* Aneurism, 2 cases; Syphilis of Liver, 2 cases; Phthisical Cavity (Remarks Dr. Bench). (3) *Dr. Cotman:* Intussusception; Rupture Kidney; Osteochondroma of Pubes. (4) *Dr. Warren:* Umbilical Hernia; Hydatiform Mole; Hallux Valgus. (5) *Dr. Beach:* Obstruction after Appendix; Needle in Knee Joint; Abdominal Trauma with Obstruction (*read*) (Remarks Dr. Warren). (6) *Dr. Fitz:* Charts of Diuresis; Dilatation of Colon; Vena Cava Obstruction. (7) *Dr. R. C. Cabot:* Gastric Ulcer in Girl of Six; Paget's Disease. (8) *Dr. Benner* (for Dr. Mixter): Nitric Acid in Stomach.

A CENTENARIAN. — Mrs. Georgiana Witham, of Epping, N. H., died last week at the age of one hundred and five years. She was born in England in 1797, and came to America in childhood; she married her fourth and last husband in her ninety-seventh year.

Reports of Societies.

AMERICAN ORTHOPEDIC ASSOCIATION.

SEVENTEENTH ANNUAL MEETING, HELD IN WASHINGTON, D.C., MAY 12, 13 AND 14, 1903.

(Concluded from No. 3, page 79.)

SECOND DAY — (*continued*).

PERIPHERAL PALSIES FOLLOWING MANUAL REPLACEMENT OF THE CONGENITALLY DISLOCATED HIP.

DR. HENRY LING TAYLOR of New York read this paper. He said that since Dr. Lorenz' visit to this country more force had been used in the reduction of this dislocation and in stretching the contracted tissues, and the position of retention had been more extreme. In the cases that he had observed in the past three or four months total paralysis of the quadriceps had been a not uncommon sequel of the operation, and in two instances total paralysis of the muscles supplied by the anterior tibial nerve had been noted. These peripheral palsies were a common cause of the difficulty experienced by some patients in walking after the operation. Nine cases were reported.

DR. ROSWELL PARK of Buffalo, in opening the discussion on the foregoing papers, pointed out the folly of calling this rather formidable method a "bloodless" one.

DR. JAMES E. MOORE of Minneapolis spoke in the same vein, calling attention to the attendant dangers and to the probability that some of these cases would do better from clean, cutting operations.

DR. V. P. GIBNEY of New York also took the position that this method was one fraught with considerable danger.

DR. N. M. SHAFFER of New York said he did not consider the Lorenz operation any more brutal than osteoclasis.

DR. GEORGE B. PACKARD of Denver showed skiagraphs of four of the six cases that had been operated on in Denver by Lorenz. Two of these skiagraphs showed the hip in perfect position, two others showed anterior transposition.

DR. JOHN RIDLON of Chicago was of the opinion that the Lorenz operation was the best known single operation for this class of cases. Of the 21 cases upon which Lorenz had operated it was already known that in six replacement had not been secured, and that in two out of the six fracture of the femur had occurred. He had taken the plaster off four other hips, with the following results: (1) In a child of four the hip was in anterior transposition and the joint quite loose; (2) in a child of four there was anterior transposition with a firm joint; (3) a double dislocation, one hip appeared to be in the socket; (4) there was a fracture through the neck of the other femur, and that bone was on a level with the greater trochanter and posterior and to the outer side of it. In one case in which replacement had been effected the perineum was torn.

DR. B. S. MCKENSIE of Toronto called attention to the fact that Lorenz did not claim that his was a perfected operation, and that he had heard Lorenz make the statement that in double dislocations the

result should be successful in 25%, and in single dislocations in about 50% of the cases.

DR. ARTHUR J. GILLETTE of Minneapolis said that it was generally assumed that congenital dislocation of the hip was very disabling, but that such was not by any means always the case.

DR. DEFOREST WILLARD of Philadelphia said that since Lorenz' visit he had done the operation with better results than before. The fact that congenital dislocation of the hip was associated with a defect both of the acetabulum and of the femoral head and neck made it very probable that within a year after the child began to walk many of these cases would relapse. The method under discussion was far from being "bloodless," for a torn muscle bled more profusely than one incised with a tenotome. These manipulative measures would probably be reinforced in the future by division of the adductors.

DR. A. J. STEELE of St. Louis cited a case upon which Lorenz had refused to operate, yet by prolonged traction, coupled with division of the adductors, it had been found possible to reduce both hips.

SIR WILLIAM HINGSTON of Montreal expressed his delight at the impartiality and candor displayed in this discussion, and remarked that it was not Lorenz, but his method, that was on trial.

DR. BRADFORD, in closing the discussion, said that he had found the ligamentum teres present in a considerable proportion of the young children. He wished to take this opportunity to say that he was now of the opinion that in a communication made some years since he had exaggerated the importance of a folding in of the capsule as an obstacle to reduction.

THIRD DAY — THURSDAY, MAY 14.

A TREATMENT OF OSTEITIS DEFORMANS AND OSTEO-ARTHRITIS.

DR. FRANK E. PECKHAM of Providence read this paper. The paper contained a report of four cases of osteitis deformans and one of osteo-arthritis successfully treated by superficial cauterization of the skin around the diseased area. This cauterization had been done once a month, and midway between a small cantharidal blister had been applied over the spine at a point corresponding to the nerve center of the part involved.

DR. GOLDTHWAIT remarked that it was well known that counter-irritation in these cases would give relief, and that for a long period the disease would remain quiescent; hence he thought the treatment advocated in the paper had effected only temporary benefit.

AN UNUSUAL CASE OF POTT'S ABSCESS.

DR. STEWART LEROY MCCURDY of Pittsburg reported this case, the essential feature of which was the incision of the abscess below Poupart's ligament and the demonstration by means of injections of methylene blue of a direct communication. The patient freely expectorated the colored matter.

BONE WIRING FOR RECENT AND UNUNITED FRACTURES, WITH REPORT OF CASES.

DR. MCCURDY also presented this paper, together with an instrument used to cut the ends of the bone. The chief points were: (1) Wiring of bone while the ends remained down in their normal position, thus reducing the disturbance of the periosteum to the minimum, and preserving nutrition and preventing necrosis; (2) the use of iron, a metal naturally present in the system, for silver, a foreign substance; (3) the anchoring of the fragments of bone to external bridge work, with the object of retaining them in position during repair.

A FURTHER STUDY OF THE MECHANICS OF ROTARY LATERAL CURVATURE OF THE SPINE.

DR. R. W. LOVETT of Boston was the author of this paper. He said that he had succeeded in demonstrating by experiment that the vertebral bodies when deprived of the articular cartilages acted mechanically as any flexible rod permanently bent in one plane. It could not, therefore, be bent to one side without twisting, neither could it be rotated or twisted without acquiring a lateral curvature. A left lateral curvature was acquired by twisting to the right, and the reverse by twisting to the left. This curve was constant and marked. It seemed possible that this connection of twisting and lateral curvature might explain certain features of scoliosis, and that both active and passive twisting movements might be used in the treatment of distortion. It was not yet possible to state the therapeutic value of this method in cases having fixed curves.

TREATMENT OF LATERAL CURVATURE OF THE SPINE.

DR. GWILYM G. DAVIS of Philadelphia read this paper. He said that as methods of treating lateral curvature were at present in a transitional stage it was of value to record personal experiences. He advised confining the patient to bed for a large part of the time, with the object of overcoming body weight. While the patient was in bed an effort should be made to assist the straightening of the spine by the use of position, weight extension to the head and by the lateral pressure of bands. The patient should rise daily and take suitable gymnastic exercises; and walking cases should not only have the exercises, but, if the deformity were marked, should wear braces.

A CONSIDERATION OF THE PROPER ARRANGEMENT OF THE CLOTHING IN GROWING CHILDREN WITH REFERENCE TO THE PREVENTION OF FAULTY ATTITUDES.

DR. J. E. GOLDTHWAIT of Boston presented the results of a study he had made of this subject. He pointed out that the normal position, with the shoulders square, could not long be maintained if the clothing, representing a weight of from three to five pounds, were supported on the tips of the shoulders, as was commonly the case. This defect in dress led to stoop shoulder, flattening of the chest, protrusion of the abdomen and of the head, and consequently led to muscle strain, particularly of the spinal muscles, weakness, and frequently to lateral curvature. He exhibited several different styles of garments commonly worn by children, and pointed out the good and bad points in each. The point to remember was that when the clothing was supported on the base of the neck, and not on

the tips of the shoulders, this muscle strain was avoided. In the adult male the weight of the clothing was borne on the base of the neck, if the suspenders were properly adjusted.

SPASTIC PARALYSIS. — SPASTIC PARALYSIS TREATED BY TRANSPOSITION OF THE HAMSTRING TENDONS.

DR. BERNARD BARTOW of Buffalo reported a case of this kind. The patient was a boy of eleven years with spastic double hemiplegia, involving especially the lower extremities. The spasticity had been first noticed at the age of three months. There was associated structural shortening with spasticity in the hamstrings, and the flexors and adductors of the thighs and the leg groups were strongly spastic during movements. The patient could not stand erect or maintain the sitting position except with difficulty. The development of the child was backward, and mentality was enfeebled. On June 9 and 20, 1902, he had operated, transplanting the hamstring tendons to the quadriceps, and correcting the malposition of the knee. This treatment was followed by rapid mental improvement, and extension power in the quadriceps was apparent after three months. Five months after the operation the patient was able to walk with the aid of crutches, and four months later he was able to walk three quarters of a mile. Before the operations he had never been able to walk in the usual way.

THE SCOLIOTONE, A MACHINE FOR ELONGATING THE SPINE AND LESSENING THE ROTATION IN LATERAL CURVATURE.

DR. COMPTON RIELY of Baltimore exhibited this apparatus, and presented a paper. The author reviewed the anatomy, mechanics and pathology of scoliosis. He was of the opinion that the muscles of the back had been unjustly accused of being responsible for the production of scoliosis. There seemed to be almost invariably in these cases an asymmetry in the two sides of the pelvis, a fact which had not received general attention. The anterior superior spine was commonly half or three quarters of an inch higher on the convex side. Attention was called to the importance of obliterating mechanically the element of lordosis as a preliminary to the lessening of the lateral rotation deformity. In the scoliotone the direction of the correcting force was adaptable equally to the lateral deviation and rotation, or chiefly to one or the other element.

HOME APPARATUS FOR FORCIBLE CORRECTION OF LATERAL CURVATURE.

DR. R. W. LOVETT exhibited a simple and cheap device intended to be used at home for the forcible correction of such deformities.

DR. A. B. JUDSON of New York opened the discussion. He said that a brace applied to produce antero-posterior pressure would be useful in treatment, although not practically efficient for absolute reduction of the deformity. A column, curving antero-posteriorly and at the same time laterally, might be said not to have two curves but rather one, partaking of antero-posterior and lateral qualities. This was not necessarily attended with rotation.

DR. B. S. MCKENSIE remarked that the maximum force could be applied by suspending the weight entirely by the spine and applying a lateral force by means of a girdle until the body was drawn to an oblique position represented by an angle of 45° or 50°.

DR. N. M. SHAFFER suggested a new operation for arresting the progress of the deformity by producing a synostosis in the contiguous articular processes.

BREAKING DOWN OF THE FOOT IN TRAINED NURSES. A SERIES OF 500 OBSERVATIONS ON NORMAL AND DISABLED FEET.

DR. R. W. LOVETT of Boston presented this communication, based on an experience in the observation of the nurses entering a large general hospital during a period of eight years. He found that the foot broke down in about 60% about two months after entering the school, and that whereas the milder cases could be relieved by the use of felt pads and foot plates, the more severe ones required to rest in bed for a time. The only element that had assisted him at the first examination in predicting the resisting power of the feet in a given case was the extent of bearing surface as seen through glass. The breaking down of the feet was largely due to general causes, and could be partially prevented by the wearing of proper shoes.

OFFICERS AND PLACE OF MEETING.

President, DR. REGINALD H. SAYRE; First Vice-President, DR. J. E. GOLDTHWAIT, Boston; Second Vice-President, DR. G. G. DAVIS, Philadelphia; Secretary, DR. JOHN RIDLON, Chicago; Treasurer, DR. E. G. BRACKETT, Boston.

The next meeting will be at Atlantic City in June, 1904.

Recent Literature.

Obstetrics. Volume V, in the Practical Medicine Series of Year-Books. Edited by REUBEN PETERSON, A.B., M.D. Chicago: The Year-Book Publishers. April, 1903.

The present volume of obstetrics is one of a yearly series of ten, issued at monthly intervals, and covering the entire field of medicine and surgery. A similar volume on obstetrics in the same series was favorably reviewed in this column a year ago, and the present work covers the field since the publication of last year. The same general plan has been followed by the editor of abstracting important articles on obstetrical subjects, as they have appeared in the current periodicals in English and foreign languages. The editor has endeavored to make the two volumes supplementary, the one of last year and this year, and consequently those subjects considered at length in the former have been given but little space this year, and *vice versa*. Very few comments on the different articles are made by the editor. The book is of especial value to those particularly interested in the subject of obstetrics as well as to the general practitioner, as an epitome of the year's progress.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JULY 23, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

MEDICAL LEGISLATION OF 1903.

DURING the legislative session of the General Court of Massachusetts, which closed on Friday, June 26, several acts were passed which are of greater or less interest to the medical profession of the State. None, however, of this character were enacted during the first four months of the session, the first act having any interest to medical men being Chapter 305 of the Acts of 1903, which is entitled "An Act Relative to Returns of Records of Deaths by Clerks of Cities and Towns." This act provides that the clerks of cities and towns shall transmit returns of deaths to the Secretary of State monthly, instead of after the close of the year as heretofore. This is entirely in harmony with the advice of the census authorities at Washington, as presented in their recent pamphlet, urging a uniform system of registration in the different states, and will tend to make the work of the central office more efficient and more prompt in its collection and publication of registration material.

Chapter 306 is entitled "An Act Relative to Infected Articles," and is a modification of a very old law which was enacted in 1751. It provides that "for any article of furniture or wearing apparel ordered to be destroyed by an order of the Board of Health the city or town may recompense the owner to an amount not exceeding fifty dollars." This refers, in the words of a preceding section, to articles "infected with any disease dangerous to the public health."

Chapter 358 provides for an investigation by the State Board of Health "of the dumping of garbage and rubbish in the harbors and along the seacoast of Massachusetts Bay." The board is authorized by this act "to report its findings to the General Court, with such recommendations as it may deem expedient to provide for the inspection and regulation of such dumping, and to prevent the strewing of the shores with offensive material, whereby a nuisance is created."

Chapter 361 is one of the many acts relating to food inspection, and provides for definite penalties for fraudulent sales of so-called "renovated butter," varying from $25 to $500, or imprisonment, according to the extent of the crime and the discretion of the judge in whose court the victim happens to be arraigned.

Another act of the same class, Chapter 367, provides that employees or clerks engaged in selling food or drugs shall not be punished for violation of the adulteration acts "unless such violation was intentional on the part of the said employee."

Chapter 383 is entitled "An Act Relative to Separate Systems of Drainage," and provides for a definite separation of storm waters and surface water from the sewage of cities and towns, wherever separate sewerage systems exist.

Chapter 400, entitled "An Act Relative to the Care of the Insane," provides that the State Board of Insanity may by agreement with the local authorities, and at a limited cost for care and treatment, "place insane persons of the chronic and quiet class in the almshouses of cities and towns, under the care of the proper local authorities."

By the provisions of Chapter 467 an additional annual appropriation is made of $1,000 for the enforcement of the acts relating to food and drug inspection. This appropriation was made on account of the act passed last year requiring the State Board of Health to conduct the work formerly done by the State Assayer of Liquors, for which no appropriation had been made in 1902.

The enactment of Chapter 480, which received the Governor's approval and became a law on the last evening of the legislative session, deserves more than a passing notice. This act is entitled "An Act Relative to the Production and Distribution of Antitoxin and Vaccine Lymph," — and provides an amendment to Section 4 of the organic act, creating the State Board of Health and defining its duties, by which the board is authorized "for the use of the people of the Commonwealth, to produce and distribute antitoxin and vaccine lymph."

Early in the session of the previous year, and while the outbreak of smallpox was at its height, a bill was introduced upon petition of Dr. Durgin, chairman of the Boston Board of Health, providing for the production of vaccine lymph by the State Board of Health.

After several lengthy hearings before the Legislative Committee on Public Health, at which evi-

dence was presented showing the need of better provision for vaccine production than any which then existed in the State, the opponents of the measure so far succeeded in their attempts to defeat it as to secure the enactment of a resolve requiring the State Board of Agriculture to investigate the practicability of maintaining a vaccine establishment at the Agricultural College in Amherst, and to report upon the same to the next General Court, thus deferring the settlement of the question to another year.

At the beginning of the session of 1903 the question was reopened by the report of the Board of Agriculture favoring the establishment of a vaccine plant at Amherst. The Druggists' Association was represented by Mr. W. W. Bartlet, while the manufacturers of antitoxin and vaccine lymph from other states maintained a corps of agents at the State House throughout the early part of the session. On the other hand, the Norfolk District Medical Society took the initiative, and with other medical organizations secured the services of Mr. V. C. Lawrence, to whom very largely the final successful issue of the movement to give the State Board of Health authority to produce and distribute antitoxin and vaccine lymph is due. He was seconded in his efforts by the active assistance of President Eliot, Dr. S. H. Durgin and other prominent men, and by the petitions of many district medical organizations and local boards of health.

PARATYPHOID FEVER.

THE term "paratyphoid" was used first by Achard and Bensaude. In 1896 they reported two cases which clinically resembled typhoid fever, but they called them paratyphoid infections because from the urine of one patient and from a suppurative sterno-clavicular joint of the other they obtained a micro-organism which closely resembled the typhoid bacillus but was not identical in its cultural reactions. Little attention was paid to this communication until the publication, several years later, of the carefully studied cases of Gwyn and Cushing in this country and of Schottmueller in Germany. During the past eighteen months many cases of infection with the paratyphoid bacillus have been recognized. Up to February, 1903, Pratt[1] was able to collect eighty-one cases from the literature and gave the notes of three additional cases which occurred in Boston. No other cases have been reported from New England, but during the past few months instances of paratyphoid fever have been observed in places as widely separated as Havana, Prague and Chicago.

[1] Boston Med. & Surg. Journ., 1903, cxlviii, p. 137.

The bacillus is intermediate in character between the typhoid and colon bacilli, and the term "paracolon" is sometimes applied to this micro-organism, but as it is more closely related to the typhoid than to the colon bacillus, and as it produces typhoidal symptoms, the name "paratyphoid" seems preferable. The chief cultural property which distinguishes it from the typhoid bacillus is its power to form gas from glucose.

The disease cannot be distinguished by the symptoms alone from typhoid fever. All the typical features of the typhoid symptom-complex may be present. The fever usually lasts three or four weeks. Brion from his analysis of the recorded cases state that rose spots and an enlarged spleen were noted in eighty per cent. of the cases and in thirty per cent. the urine gave the diazo reaction. Diarrhea with pea-soup discharges occurred in eighteen per cent. As a rule the disease runs a milder course than typhoid fever, although the variety and frequency of the complications has been a striking feature.

Only three undoubted cases of paratyphoid fever have resulted fatally. In none of these were the intestinal lesions of typhoid fever present. The absence of general involvement of the lymphatic apparatus of the intestine clearly distinguishes the disease from typhoid. There was no ulceration or swelling of Peyer's patches and the mesenteric lymph nodes were not enlarged. In one of the cases there was a slight diphtheritic enterocolitis, while in the recent case of Lucksch there was hyperplasia of the solitary follicles of the colon, several of which were ulcerated. The lesions in these two cases resembled those of dysentery rather than of typhoid fever. As in other acute infectious diseases there is parenchymatous degeneration of the viscera and a splenic tumor. Early in the disease the paratyphoid bacilli are found in the blood in large number. They have also been obtained during life from the urine, feces, sputum, rose spots and spleen.

The source of the disease has been traced in two instances to the drinking water.

The surest way of making the diagnosis is to cultivate the bacillus from the blood. The withdrawal of 10cc. of blood from one of the large veins of the arms is a simple and safe procedure if aseptic precautions are taken. In some cases the diagnosis has been made by isolating the paratyphoid bacillus from the urine or feces or some localized lesion and then demonstrating that the individual's blood in high dilution agglutinated the bacillus. If the blood from a suspected case of paratyphoid fever agglutinates a paratyphoid bacillus in very high dilution and fails to agglutinate

the typhoid bacillus at all or only in low dilution the diagnosis of paratyphoid infection can be made. Although the blood of a paratyphoid patient usually does not clump the typhoid bacillus even in as low a dilation as 1 : 10, recent observations have shown that cases do occur in which the paratyphoid serum does clump the typhoid bacillus in as high a dilution as 1 : 100. There are two species of paratyphoid bacilli, and inasmuch as the blood of an individual infected with one species may fail to clump the other, cultures of both should be used in making the tests. The fact that the prognosis is more favorable in paratyphoid fever than in true typhoid makes a correct diagnosis a matter of practical importance.

SUPPRESSION OF THE NEWS OF SUICIDES.

IT is reported that an attempt is to be made in Cleveland, Ohio, to suppress details in all cases of suicide. Such a course of procedure is certainly justified by the facts at our disposal regarding the contagion of acts of violence. The effect of suggestion in suicide, as in lynching and other crimes against the individual or society, is a potent influence which should always be taken into account. It would no doubt be very much to the public benefit if details of such crimes or misfortunes, often drawn out to wholly unnecessary length in our daily papers, could be completely suppressed. How far this is compatible with our ideas of freedom of the press and liberty of public expression is open to doubt, but there can be no question that a very great incentive to the unfortunate occurrences which form so conspicuous a part of certain of our daily papers would be removed could a general suppression of all such news be enforced.

MEDICAL NOTES.

DENGUE IN HAWAII. — It is reported that an epidemic of dengue has appeared in Hawaii, with upwards of fifteen hundred cases, but up to this time no deaths have occurred from the disease.

TYPHOID IN ITHACA. — The report comes that typhoid fever, although naturally diminished in amount, is still prevalent in Ithaca, and that the water supply is not yet above suspicion. July 16 nine cases were reported as ill with the fever, with several suspected cases. It is alleged that the Ithaca Water Company is still serving the city with infected water through a failure to protect its watershed. Artesian wells are being driven with a capacity nearly sufficient to supply the city.

COCAINE HABIT AMONG NEGROES. — At the annual Hampton Negro Conference, which began its sessions July 15, the question of the growth of the cocaine habit among negroes was discussed by Dr. J. W. Prather. After a report on the diseases to which the negro is liable, he called attention to the alarming growth of the cocaine habit, and pointed out the fact that upwards of 200,000 negroes are addicted to the cocaine habit or the use of other narcotics. In a recent number of the *Medical Press* refefence is made to the increasing spread of the cocaine habit, and its prevalence among negroes is commented upon.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 22, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 31, scarlatina 22, typhoid fever 21, measles 22, smallpox 0.

MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending July 18 was 215 as against 189 the corresponding week last year, showing an increase of 26 deaths, and making the death-rate for the week 18.58. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 31 cases, 5 deaths; scarlatina, 20 cases, 3 deaths; typhoid fever, 16 cases, no deaths; measles, 23 cases, no deaths; tuberculosis, 34 cases, 18 deaths; smallpox, no cases. The deaths from pneumonia were 25, whooping cough 1, heart-disease 21, bronchitis 3, marasmus 1. There were 13 deaths from violent causes. The number of children who died under one year was 52; under five years, 67; persons over sixty years, 47; deaths in public institutions, 79.

MIDDLESEX SOUTH DISTRICT MEDICAL SOCIETY. — A recent meeting of the Middlesex South District Medical Society was held at Pemberton, Boston Harbor, in which certain matters other than medical claimed the attention of the members.

NEW YORK.

STEVENS' TRIENNIAL PRIZE. — The Stevens' triennial prize of Columbia University for original research was awarded to Drs. L. Pierce Clark and Thomas P. Prout of New York for an essay upon "Status Epilepticus: A Clinical and Pathological Study of Epilepsy."

CLAIMS OF A VETERINARIAN SUSTAINED. — In special term at Troy on June 20, Justice Howard decided, in spite of the opposition of the State, represented by Deputy Attorney-General Church, that the State Board of Veterinary Medical Examiners

must recommend the issue by the board of regents of a veterinarian certificate to Albert L. Harris of Nassau, Rensselaer County. The question at issue was whether the examiners could refuse to report as satisfactory Harris' alleged proofs of at least three years' practice of veterinary medicine prior to the year 1890, and Justice Howard's decision seems to make the applicant's affidavit to that effect sufficient. The case is important as probably involving all similar cases of medical practitioners, and it is said that the State is likely to appeal.

ST. JOHN'S GUILD FLOATING HOSPITAL. — The first trip of the twenty-eighth season of the St. John's Guild Floating Hospital took place on July 7. About a thousand women and young children were carried, and a number of very ill children were left at the Guild's Seaside Hospital at New Dorp, Staten Island. Owing to lack of sufficient funds, but one boat instead of two will be operated this season.

A CENTENARIAN. — Thomas Thompson, a negro who was born a slave in Moonachie, N. J., died at his home on the Hackensack Meadows, Hudson County, N. J., on July 8, at the reputed age of one hundred and two years.

DEATHS FROM HEAT. — During July 9 and 10 forty-four deaths from the direct effects of the heat, besides a large number of non-fatal prostrations, were caused in New York.

MANILA LETTER.

SPECIAL CORRESPONDENCE.

THE CHOLERA SITUATION. — PLAGUE. — LOSS TO BOARD OF HEALTH BY FIRE. — LOCUSTS. — CURIOUS BELIEFS ON MEDICAL MATTERS.

THE cholera situation continues to show marked improvement. The islands are quite widely infected, but the people are more generally taking precautions and an improved sanitary organization is enabling the Board of Health to handle the situation more effectively. The amount of devastation done by the disease is gradually being reduced to figures, as a number of the Board of Health doctors are making investigations in regions from which no reports have previously come. Their figures include the entire period of the epidemic. In one daily report recently no less than 1,040 deaths were reported, but all except about 50 of these deaths occurred some months ago. The total number of deaths from cholera now reported reaches more than 86,000. A few cases occur daily in Manila, but only four or five where a year ago at this time there were a hundred deaths daily. As these cases have nearly all occurred along the water front among boatmen and laundresses, and a large part of these developed on board boats lying in certain parts of the river where there was slack water not greatly affected by currents or tides, the attention of the health authorities was called to the probability of the Pasig being the chief, if not almost entirely the sole source of infection; in one instance occurring in the Santa Ana District of Manila, five persons drank Pasig River water on June 3, and all were dead of cholera on June 5. While in a certain number of cases infected food seemed to play an essential part, and the Filipinos themselves attributed the disease to such foods. The fact of the disease occurring in certain restricted classes seemed to point to a subsequent infection of the food after it had left the markets. Investigation showed that the marine and river population usually washed their food in the Pasig River water. An elaborate system of investigation of this water as to the presence of the cholera bacillus was at once instituted by two representatives of the Board of Health working independently. Samples were collected from various parts of the river in and near Manila, and of 20 such specimens 18 showed the presence of the cholera bacilli in large quantities. The water was first tested with the "cholera red" test, and the organisms subsequently isolated. As little as one half of a cubic centimeter of river water gave in many cases a strong reaction. The bacilli were found in the slack water and particularly in the shallow reaches used as places of anchorage for cascoes awaiting employment, and were not found in the main current. In view of this discovery of the cholera bacillus in the Pasig, the Board of Health has just instituted more strict measures for enforcement of the standing prohibition of the use of Pasig water. While nearly all of the natives use water from the city supply for drinking and cooking purposes, many bathe and wash clothes and food in the Pasig, and in this way acquire the infection. Bathing and swimming is particularly an important factor, and with as little as half a cubic centimeter giving a strong reaction it is hard to see how a swimmer could avoid taking at least that much river water into his mouth, and thus acquiring an infection. The patrolling of the river by sanitary inspectors will probably much reduce the use of its waters, and proportionately decrease the number of cases of the disease. Every possible effort is being taken to prevent the contamination of the city water supply, and so far with excellent success. The sharp epidemics which have lately occurred in certain small provincial towns show what might be expected if the water supply here should become infected. In Apani, for instance, every water sample sent to Manila for analysis showed large numbers of cholera bacilli present, and the cholera mortality in that place has been very high. When the authorities at Apani were notified of the continued presence of the cholera bacilli in their water supply, they illustrated the general helplessness of the natives in respect to sanitary matters, for, on being directed to boil their drinking water and cook their food thoroughly, they promptly replied with a request that the soldiers stationed at that place be directed to distill water for their use. This is only equalled by the request of natives on the watershed of the Manila water supply, who asked that the soldiers acting as sanitary guard look after their carabao while the natives went to mass. At the present time cholera appears to be worst in the province of Albay, Luzon and in the island of Mindanao, and it would appear as if the number of deaths occurring was considerably in excess of those reported. As everywhere at this time, the disease assumes a most virulent form, and nearly all those attacked quickly die. The concealment of cases is a most serious drawback to the work of the sanitary authorities, as they are thus prevented from taking proper preventive measures before the disease has assumed an epidemic form.

The plague situation is also very gratifying and shows excellent results, due to the general inoculation of the Chinese, the catching of rats, fumigation of ships and destruction of plague houses. During the month of May there were but twenty-five cases of plague in Manila, while in Hong Kong there were nearly four hundred and fifty. For the single week ending May 23, the Hong Kong plague report showed one hundred and thirty-six cases, among them a number of Europeans. As the outbreaks in the two cities started at the same time and progressed up to a certain point at about the same rate in respect to the number of cases, it is fair to presume that the admirable showing of Manila in comparison with Hong Kong is the result of the much more strict measures instituted by the Board of Health here as soon as it was apparent that a severe epidemic was threatening. Too much credit cannot be given to Major Carter, the commissioner of health, for the excellent results obtained in cutting down plague and cholera,

and the local press is very enthusiastic over the sanitary work being done by the health authorities here. Even the natives, who are always rather loth to admit the fact that American reforms are productive of good, are beginning to recognize the excellent results attained by the health authorities.

The loss of property by the Board of Health by the recent fire has been determined at nearly $100,000, in spite of which the sanitary work has gone on with practically no interruption. Rebuilding of the buildings destroyed is going on rapidly, and with an idea to future convenience and permanence. A large amount of material for use in connection with the pail system of disposal of excreta will have to be purchased. This matter of disposal of excreta is being taken up vigorously, and a committee has been appointed to draw up plans and specifications for the establishment of sewers, disposal of excreta, improvement of the esteros and the sanitation of the low-lying submerged lands in and around Manila. As soon as the report of this committee has been rendered, it is expected that the work of improvement will be pushed as rapidly as possible.

Locusts are again devastating the fields of the provinces of Pangasinan, Tarlac and Nueva Ecija, and the health authorities are making every effort for their destruction. The ignorant peasants are ascribing the presence of the locusts to all kinds of fantastic causes. Some say that God is angered by the coming of Protestants into fields that were once under exclusive control of the Church of Rome; others, the adherents of the new Filipino Independent Church, intimate darkly that there is some connection between the appearance of the locusts and the arrival of Archbishop Guidi, the papal delegate, in the Philippines, and say frankly that there is no hope of getting rid of the locusts until Mons. Guidi departs. Some of the adherents of the Catholic Church, on the other hand, opine that the locusts are sent as a just punishment upon the Filipinos for joining the new church started by Aglipay. Still another party says that the Spanish friars are to blame, and there are many who believe that the Union Observa, a new political party, is the cause, as it was established and the locusts appeared at about the same time. These whimsical ideas are quoted to show the ignorance and credulity of the Malay mind, the workings of which are frequently beyond the comprehension of the American.

Curious beliefs of this sort are particularly entertained in respect to medical matters, and often create serious obstacles to the health authorities in their efforts to prevent disease. Instruction and education must be given before the people can be brought to a realizing sense of the necessity for following even the most elementary sanitary rules. A good example of this fact is found in a trial now going on at Iloilo of a native who circulated a story to the effect that the Americans were poisoning the wells during the late cholera epidemic there. The sanitary authorities had him arrested, and now the government is prosecuting him under the charge of sedition, alleging that his words had a dangerous effect upon peaceable conditions and were inciting the Filipinos to rise against the government. It will be much to the advantage of sanitary work here if he is severely punished if proven guilty, for the ignorance of the natives is too frequently taken advantage of by more educated individuals, who are against the government or opposed to sanitary reforms.

PARATYPHOID FEVER.

BOSTON, July 3, 1903.

MR. EDITOR: "Paratyphoid" is at present frequently applied to cases of typhoid fever, particularly in the culture reports by the Bacteriological Laboratory. The majority of the profession are uninformed as to what the term denotes pathologically, and I am one of that number, although I have consulted recent literature on typhoid, and have conferred with several of the eminent members of the medical profession in our city. Can you not serve the profession by giving them light editorially?

Deaths reported, 3,849; under five years of age, 1,545; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,242, acute lung diseases 301, consumption 307, scarlet fever 41, whooping cough 24, cerebrospinal meningitis 12, smallpox 13, erysipelas 6, measles 34, typhoid fever 48, diarrheal diseases 686, diphtheria and croup 62.

From whooping cough, New York 7, Chicago 4, Philadelphia 5, Baltimore 2, and Boston, Lowell, Cambridge, Springfield, Somerville and Quincy, 1 each. From erysipelas, New York 4, Chicago 1, Philadelphia 1. From smallpox, Philadelphia 11, Pittsburg 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending June 27, the death-rate was 14.3. Deaths reported, 4,137; acute diseases of the respiratory organs (London) 150, whooping cough 84, diphtheria 44, measles 137, smallpox 13, scarlet fever 48.

The death-rate ranged from 5.3 in Ipswich to 27.2 in Great Yarmouth; London 13.5, West Ham 11.1, Brighton 8.7, Portsmouth 13.4, Southampton 12.3, Plymouth 10.2, Bristol 12.8, Birmingham 16.6, Leicester 14.4, Nottingham 17.4, Bolton 17.4, Manchester 18.0, Salford 18.6, Bradford 15.8, Leeds 12.9, Hull 15.0, Newcastle-on-Tyne 17.6, Cardiff 10.6, Rhondda 13.9, Liverpool 18.8, Hornsey 9.3, Coventry 24.4.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JULY 16, 1903.

PERRY, J. C., passed assistant surgeon. Granted leave of absence for one month from July 14. July 10, 1903.

ROSENAU, M. J., passed assistant surgeon. To proceed to Boston, Mass.; Philadelphia, Marietta and Swiftwater, Pa.; Detroit, Mich.; St. Louis, Mo.; Milwaukee, Wis.; Chicago, Ill., and Baltimore, Md., for special temporary duty. July 10, 1903.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for one day, July 17. July 15, 1903.

CLARK, T., passed assistant surgeon. Granted leave of absence for seven days from July 13, 1903, under paragraph 191 of the regulations.

MCCLINTIC, T. B., assistant surgeon. To proceed to Atlantic City and Point Pleasant, N. J., for the purpose of making physical examinations of keepers and surfmen of the Life Saving Service. July 15, 1903.

To proceed to Tuckerton, N. J., for the purpose of making physical examinations of keepers and surfmen of the Life Saving Service. July 16, 1903.

TROITER, F. E., assistant surgeon. Granted seven days' extension of leave of absence from July 13. July 11, 1903.

WILLE, C. W., assistant surgeon. To proceed to Ocean City, Md.; Chincoteague Island and Olney, Va., for the purpose of making physical examinations of keepers and surfmen of the Life Saving Service. July 15, 1903.

BARNESBY, P. N., acting assistant surgeon. Granted leave of absence for two weeks, on account of sickness, from July 2. July 8, 1903.

HICKS, W. R., acting assistant surgeon. Granted leave of absence for three days from July 14. July 15, 1903.

SWEETING, C. B., acting assistant surgeon. Granted leave of absence for thirty days, on account of sickness, from July 10. July 13, 1903.

TUTTLE, JAY, acting assistant surgeon. Department letter granting Acting Assistant Surgeon Tuttle leave of absence for thirty days, amended so as to be effective July 3. July 10, 1903.

WELDON, W. A., acting assistant surgeon. Granted leave of absence for fifteen days from July 11. July 11, 1903.

BOARDS CONVENED.

Board convened to meet at the marine hospital, Port Townsend, Wash., July 17, 1903, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon J. H. Oakley, chairman; Passed Assistant Surgeon N. H. Foster, recorder.

Board convened to meet at the marine hospital, Chelsea, Mass., July 21, 1903, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon R. N. Woodward, chairman; Assistant Surgeon W. C. Rucker, recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY. WEEK ENDING JULY 18, 1903.

H. L. LAW, surgeon, retired. Ordered to additional duty at Marine Recruiting Station, Providence, R. I.

H. L. BROWN, assistant surgeon. Appointed assistant surgeon with rank of lieutenant, junior grade, from June 29, 1903.

J. C. THOMPSON, assistant surgeon. Detached from the "Columbia" and ordered home and to wait orders.

C. H. DELANCY, assistant surgeon. Detached from the Navy Yard, Norfolk, Va., and ordered to the "Columbia."

G. R. PLUMMER, acting assistant surgeon. Ordered to Naval Station, Key West, Florida.

C. H. T. LOWNDES, surgeon. Detached from the Naval Station, San Juan, Porto Rico, and ordered home and to wait orders.

G. PICKRELL, surgeon. Ordered to Naval Station, San Juan, Porto Rico.

H. N. T. HARRIS, surgeon. Orders of July 8 modified; detached from "Glacier" and ordered to Navy Yard, Pensacola, Fla., July 18.

W. H. BUCHER, passed assistant surgeon. Detached from Navy Yard, Pensacola, Fla., and ordered to Washington, D. C., July 21, for examination for promotion, and thence to San Francisco, Cal., to take passage on "S. S. Siberia," sailing August 8 for Asiatic Station, for duty at Navy Yard, Cavite, P. I.

J. C. THOMPSON, assistant surgeon. Orders of July 14 modified; detached from "Columbia" and ordered to "Chesapeake" July 17.

A. J. GEIGER, assistant surgeon. Detached from Naval Hospital, Navy Yard, Norfolk, Va., and ordered to Washington, D. C., for duty as recorder of Naval and Medical Examining Board now in session at Naval Museum of Hygiene and Medical School.

R. B. CHAPMAN, acting assistant surgeon. Ordered to duty with Recruiting Party, No. 6.

L. H. SCHWERIN, acting assistant surgeon. Detached from duty with Recruiting Party, No. 6, and ordered to the "Southery."

F. W. TYREE, acting assistant. Ordered to the Naval Station, Port Royal, S. C.

RECENT DEATHS.

CHARLES BLODGETT, M.D., M.M.S.S., formerly of Holyoke, died at Grass Valley, Cal., June 25, 1903, aged seventy-five years.

STEPHEN JOSEPH DUNN, M.D., M.M.S.S., of Springfield, died in Hartford, Conn., June 27, 1903.

CHARLES LANCASTER, M.D., of Plainfield, N. J., died on July 6, at the age of ninety-six years. He was well known as a literary man as well as a physician.

EDWARD V. ARMSTRONG, M.D., U. S. Navy, retired, died at the Presbyterian Hospital, New York, on July 16, from the results of tropical malarial fever, which he contracted when on service in the Philippines. He was thirty years of age. At the time of the outbreak of the Spanish-American War, Dr Armstrong was practising at Mount Vernon, Westchester County, N. Y. He promptly offered his services to the Government, and in April, 1898, was appointed an assistant surgeon in the navy. During the war he served on the "Scorpion," and at its close was assigned to duty in the Philippines. Ill health necessitated his retirement and until he came to New York about the 1st of July to undergo an operation, he resided at Mount Vernon. A year ago he married a sister of Mayor Fiske of that city.

GEORGE CHAPPELL CRAWFORD, M.D., of Brooklyn, N. Y., died on July 13, at the age of thirty-five years. He was a native of Long Island and was graduated from the Long Island College Hospital, Brooklyn, in 1894.

BOOKS AND PAMPHLETS RECEIVED.

First Principles of Otology. A Textbook for Medical Students. By Albert H. Brick, M.D. Second edition. Illustrated. New York: William Wood & Co. 1903.

A Parasite Roundworm (*Agamomermis culicis*, n.g., n. sp.) in American Mosquitoes (*Culex sollicitans*). By Ch. Wardwell Stiles.

The Type Species of the Astode Genus *Hymenolesis*. By Ch. Wardwell Stiles. Bulletin No. 13. U. S. Public Health and Marine Hospital Service. May, 1903.

La Sinorchidia nelle operazioni conservatrici del testicolo. By Dottor G. Pascole. Napoli, 1903.

Addresses.

THE SHATTUCK LECTURE.

THE SOURCES, FAVORING CONDITIONS AND PROPHYLAXIS OF MALARIA IN TEMPERATE CLIMATES, WITH SPECIAL REFERENCE TO MASSACHUSETTS.*

BY THEOBALD SMITH, M.D., BOSTON.

(Continued from No. 4, page 92.)

IN 1895 the board began the distribution of coverslips in small metal capsules upon which blood films from suspected cases were to be spread, dried and mailed to the laboratory. There the films were stained and carefully scrutinized for the malaria parasite. Since the establishment of this service many cities of the Commonwealth have created their own diagnostic laboratories, and material from the cities rarely finds its way to the laboratory of the board. Many physicians do not consider it worth the trouble to send in blood films where the fever is clearly intermittent and is cut short with quinine. In spite of the incompleteness of our records concerning the prevalence of malaria, they are quite suggestive. Since April, 1896, malaria parasites have been demonstrated in specimens from twenty-eight different towns. Some of these towns have sent specimens for three consecutive years. Very few appear but once on the list. In all, 175 individual cases were found infected. What proportion of the whole these represent I am unable to state approximately; but I am inclined to believe, from conversations with many physicians practicing in the country, that they represent only a small fraction of the actual total.

Under the most favorable circumstances the study of the distribution and epidemiology of malaria remains difficult for two reasons. The most inveterate malaria carriers know how to treat themselves with quinine, and thus the very cases which might explain the incidence of intermittent fever escape the inquirer. In the second place the very people who in other matters pertaining to the public welfare may be depended on for aid are often averse to giving information concerning malaria in their neighborhood. Dr. Bronson stated in 1871 that "as a rule men having residences or building lots for sale are, on the ague question, not above deception."

In attempting to interpret the appearance of these waves of intermittent fever we must distinguish between the original sources of the infection and the local favoring conditions. The malaria parasite is not created anew by telluric and meteorological conditions, but it comes from some pre-existing parasite. Where did it come from? In the tropics malaria is potentially present at all times. With us it appears as a rule quite unexpectedly and may again disappear. The belief was quite general that upturning of the soil was responsible in some way for the disease. That it closely follows operations involving excavations such as railroad building, grading, tunneling, and the building of dams, dikes, bridges and reservoirs is well known. The immediate popular inference was the crude, unbiological notion that the germs of malaria live in the soil. While studying the appearance of malaria along the line of construction of the Metropolitan Water System in 1897 and the epidemic in Billerica and Concord several years later, I became firmly impressed with the belief that malarial infection is imported by workmen. This theory * was suggested by experimental studies in bovine malaria which showed that all cattle from endemic regions carry the germs in their blood and that the disease can readily be produced by inoculating a little blood from these healthy, immune animals from infected districts. That workmen from malarial countries may carry the parasite in the same way perhaps indefinitely was the only theory that could satisfactorily explain the observed facts. Since that time the theory that human beings are the sources of malarial infection has become firmly intrenched. Koch [46] in his Italian investigations stated that the infected human beings must be considered the starting-point of every season's new cases. Christophers and Stevens, reporting to the Royal Society from their field of investigation on the west coast of Africa, go so far as to strongly argue segregation of Europeans from the natives, as the latter are largely carriers of the parasites.† The same authors point to the analogy between malaria and Nagana or the tsè tsè disease. A fly transmits the blood parasite of this disease from apparently healthy wild game and from buffaloes to the domestic animals imported from Europe. The latter usually contract a fatal disease. While admitting the analogy I must confess that that between human and bovine malaria is much closer. The tsè tsè parasite is a flagellate and lives free in the blood. The parasites of the two forms of malaria are sporozoa, both live in the red corpuscles and have many characters in common. Christophers and Stevens, furthermore, ridicule the idea that malaria can be acquired in regions free from human beings, and they show that there are very few places even in the heart of Africa where the explorers are not near natives.

When the theory that the laborers and not the upturned soil were responsible for malaria was first formulated in my mind I felt that in so important a matter there should be ample proof. New theories or hypotheses unsupported by facts are more dangerous than none at all when promulgated, since many are contrary to fact and if applied are certain to cause damage. It seems to me that taking into consideration the

* Delivered before the Massachusetts Medical Society, June 9, 1903.

* Was tentatively published by me in 1901 (see Lit. 47 and 63).

† "These facts are of importance as they show that the generally received idea that Europeans derive malaria from pre-existing cases in Europeans requires considerable modification. This factor, it seems to us, sinks into complete insignificance beside that of infection derived from native sources." (Rep. to Malaria Committee, Royal Society, Seventh Series.)

abundant contributory and demonstrative evidence which has been accumulating since 1897 we are quite safe, in our efforts to suppress malaria, in now taking this theory as a fact and acting upon it.

If then we focus our attention upon man as the carrier of malarial infection, and if at the same time we consider that the more "seasoning" a man has had up to a certain point the more ready he may be to have gametes in his blood after infection from a less seasoned neighbor or bedfellow, we shall be able to explain many of the peculiar freaks played by malaria in our State.

The experience of the early New Haven settlers in going through a "seasoning" process is the same as that experienced by the early settlers of the middle West. Malaria was quite prevalent during pioneer days, but it slowly declined and in many places disappeared. This decline and disappearance were usually ascribed to the drainage and cultivation of the soil. This was, to be sure, an important factor in suppressing local breeding grounds of mosquitoes, but these did not originate the germs. The latter were, in part, brought by pioneers from endemic regions in the South and transmitted to the susceptible population from the North. A third factor, which in many places and probably also in the Connecticut colonies may have been the predominant one, was the Indian. The aborigines, when exposed to malaria, must have gone through the process of immunization just as to-day the native Africans are going through this process from infancy on. Even if we assume that the adult was wholly immune and free from infection, there must have been all grades of immunity in accordance with age and frequence of exposure in any given locality. With the gradual thinning out of the natives or their forced migration, and the introduction of Peruvian bark, the malaria parasite was gradually destroyed.*

Of the outbreak in western Massachusetts, at the end of the eighteenth century, the sources of infection can be discovered only by a careful study of contemporary local history with special reference to the movement of the population and the modes of life. Even without any appreciable influx of immigrants from malarial countries, our own Southern States could have furnished at any time a sufficient quota of malaria carriers to start an epidemic under favorable local conditions. Dr. Bronson, in his quest for the origin of malaria around New Haven, found what he took to be the first case in 1863 on Cove River, in West Haven, in a sawmill. "While thus occupied (repairing in the pit and about the flume of the mill) in August,1863, in a season of drought, he [the patient] was seized with a fit of ague. *He had been at the South several years before and knew the disease, but had not had it.** According to his statement, his was the first case in that quarter and the only one that year."

The last invasion of New England by intermittent fever, beginning roughly with 1870 and extending to the present, a period which has been so well described in its various manifestations by others already referred to, was largely due to the great material development which found expression in many new public and private enterprises, such as the reconstruction of railroad beds and highways, the introduction of public water supply and sewerage plants, the building of mills, and the draining, filling and grading of suburban territory and the like. In connection with these enterprises the source of malarial infection during the last thirty years I regard as coming from the Italian, Hungarian and other immigrants from endemic foci, and the contingent of colored laborers from the Southern States.

There is a remarkable coincidence between the growth of this foreign body of immigrants and the progress of malaria in New England in these latter decades. Those who have traced its movements claim that it came from the southwest, that is, from the New Jersey coast, and spread northward and eastward. I am inclined to believe that it came from the transatlantic steamers landing their passengers in New York City.

The twelfth census gives these figures of the foreign-born population from Italy in our country since 1860:

1860 . . .	10,518	
1870 . . .	17,157	
1880 . . .	44,230	
1890 . . .	182,580	Increase 312.8%
1900 . . .	484,027	Increase 165.1%

Of that same population there were males of voting age, in —

1890	70,853 aliens
1900	133,810 „

the total number of males of voting age in 1900 being 252,534. The predominance of men is seen by comparing this figure with the total Italian population given above.† Of this large contingent Mr. Prescott F. Hall [48] states that 95% are destined for New England, New York, New Jersey and Pennsylvania. What proportion of such immigrants come from malarial districts of Italy it would be impossible to determine with any accuracy. The Commissioner of the Bureau of Labor Statistics of Connecticut is quoted by R. Mayo-Smith [49] as stating that "the Italian immigrants come almost entirely from the southern districts of Italy." In 1897 I interrogated twelve Italians living in

* It is of interest to note here that the year of the introduction of Peruvian bark by the Countess of Chinchon, 1638, witnessed the planting of the New Haven Colony. Quinine, the active principle, was not used until 1820.

* The italics are mine.

† The annual immigration from Italy was 12,354 in 1880. Fluctuating more or less during the decade, it reached 52,003 in 1890. During the following years it was usually above this figure. In 1900 the total was 101,662, of which 84,346 are reported as from southern Italy. In 1902 the total reached is the enormous sum of 180,535, of which 152,915 are from southern Italy. (From figures kindly furnished by Mr. Prescott F. Hall, Secretary of the Immigration Restriction League.)

a laborers' camp in Southborough. Five claimed to have come from Naples, three from Rome, and only one from Piedmont. Three did not give the district.

Concerning the importation and use of Italian laborers, I quote from Prof. R. Mayo-Smith the following statement:

> There has been a large number of such cases (laborers imported under contract) during the last ten years (1880–1890). Many of the Italians who have worked on our railroads have been brought by contractors for that purpose. The New York Commissioners of Labor, in 1885, found a contractor in Buffalo who admitted that he had furnished four hundred foreigners to railroad companies and other corporations during the preceding year. We hear of similar cases in New Jersey, Kansas, Iowa, and Wisconsin. The Commissioner of the Labor Bureau in the last named state asserts that in the year 1886 the state was flooded with circulars from an Italian labor and construction company in New York, offering to let men for "tunneling, grading, mining, breaking stones, laying ties, repairing washouts, laying water and gas mains," etc.

Among the other foreign immigrants from southern Europe who may bring the malaria parasite and who are of sufficient importance numerically to be considered here, are those from the basin of the Danube and its tributary, the Theiss, in Hungary. The twelfth census furnishes us with the following figures of the foreign-born Hungarians:

1870	3,737
1880	11,526
1890	62,435
1900	145,714

Of voting age, there were in —

1890	38,749
1900	72,897

Assuming that these figures are fairly accurate, there were in the United States, in 1900, over three times as many foreign-born Italians as Hungarians.*

Malaria may also be disseminated by chronically infected inhabitants of malarial districts in the South when conditions are favorable, as in camps of negro laborers. A number of cases occurred in 1897 in such a camp near West Berlin, Mass.

The thousands of immigrants from malarial regions are under ordinary circumstances absorbed without causing any appreciable increase in malaria. Those that go into the crowded quarters of our large cities are not exposed to the bites of Anopheles, excepting in rare instances. Those that go into the country districts to till the soil are not likely to create a focus of malaria, as the conditions for transmission from isolated cases are not very favorable in our climate. Under ordinary circumstances, therefore, the scattering of such potentially dangerous people over a wide territory would perhaps arouse no attention or apprehension.

There are many examples of imported malaria, known to physicians of our latitude, before whose door the spread of malaria cannot be laid. The returning soldiers of the Civil and the Spanish wars did not, so far as observations go, infect their neighborhood. Sergent,[50] after studying the subject in Paris and its suburbs, states that although there are many Anopheles in the suburbs, and some chronic cases of malaria in the city from the colonies, no indigenous cases came to the notice of the author.

When, however, a considerable number of individuals remain together, work in rural districts in proximity to breeding places of mosquitoes and sleep at night in sheds built in the open country, usually near some small body of water and wholly unprotected from the attack of the omnipresent species of Anopheles, the situation is wholly different. Under such conditions, usually, some one or more individuals carry malaria parasites. These are transmitted to the non-immune or only partially immune fellow-laborers. Opportunity for the infection of mosquitoes with gametes from the blood is ample; and, sooner or later, the infected mosquitoes find their way to the very susceptible natives of the territory where the work is going on.

We are all of us tolerably familiar with the condition I have described. It is a method employed many years ago in pushing railroad construction forward in more or less unoccupied territory where it was necessary to retain the force of men near the scene of operations. This method of carrying on work in more or less densely populated districts has been in use certainly since 1870. Dr. Bronson furnishes the following illustration for the New Haven district, which I quote verbally:

> In pursuance of this agreement they drew down the water, and when the ground was sufficiently dry, in August, 1871, set about forty men to work cutting the bushes at Pine swamp, and in a tract of about twenty acres at the head of the lake. The men were occupied some four weeks cutting and burning, during which time about half the party slept on the ground near their work. Of the whole number, only one had the fever before the job was completed, but I have heard of two or three others who had it afterward.

Dr. J. F. A. Adams quotes the following letter received from Dr. C. Seymour of Northampton, Sept. 27, 1880:

> A very large percentage of the cases have occurred at a railroad station on the Connecticut River, two miles below our village. Here is located a large sawmill, employing seventy-five men; and these have quite generally suffered. Many of them have never consulted a physician, as they know quinine cures the "shakes," and get and use it accordingly.

Dr. Z. B. Adams says that in 1885 "an Italian, a laborer upon the new conduit through Farm Pond, was sent away together with several companions suffering from the fever."

I have the microscopic records of malarial infection from several laborers' camps. Such cases were usually overlooked some years ago. If discovered they were supposed to be a product

*In 1880 the number of immigrants from Hungary was 4,363; in 1890, 22,062. In 1902 the total Magyar immigration was 23,610. In the intervening years there was the usual fluctuation, corresponding with periods of industrial depression and prosperity.

of the environment, the upturned soil, the swamp or the partly drained pond or stream about which they were at work. Many patients treated themselves. The presence of malaria was recognized only when the infection had become disseminated and had attacked the inhabitants living near by.

Occasionally the accumulation of infection goes on so rapidly that veritable epidemics are the result. The disease appears in an explosive manner like typhoid fever or cholera. A good illustration of this type of outbreak occurred in Rhode Island in 1880.[51]

On Aug. 18 a workman in the yards of the Nayatt Brick Company was taken with chills and fever. Five days later sixty workmen were affected, some with very severe symptoms. On Aug. 25 the disease reached its climax, with seventy on the sick list. About Sept. 1 there was a general lessening. On Sept. 20 nearly fifty were again on the sick list. During the season one hundred and eighty-five persons, comprising almost the entire force, had been affected. Of the workmen attacked nearly all were Canadians. They slept in two lodges near the works. The two upper stories were occupied as sleeping rooms, the highest being twenty feet from the ground. Both floors were equally affected. The epidemic came very unexpectedly, for cases of malaria in this vicinity could not be recalled by the oldest inhabitant.*

Another epidemic of a different character as regards time and topography is the celebrated New Lenox case described by Dr. J. F. A. Adams.[39b]

In 1870 the dam of the Smith Paper Company on the Housatonic River was raised three feet above the already existing four feet. In the lower half of the district influenced by this dam, which caused a setback of four miles in a direct line, water spread out irregularly to an average width of a quarter of a mile. With the daily variations in the depth of the water portions of the muddy bottom were alternately covered with water and exposed to sun and air. During the very low water in the summer and fall of 1880, coves and detached pockets of water were formed.

In the summer of 1878 intermittent fever began to prevail in the vicinity of this reservoir. The first cases appeared close to the river on the east side at the foot of the mountains bordering the reservoir.

Of a population of eight hundred souls about three hundred and fifty-three were attacked up to Oct. 1, 1882. Up to 1880 cases had appeared in every one of the twenty houses on the east side of the river between the dam and the Pittsfield line. In some houses as many as six cases occurred. The surrounding towns were comparatively free from malaria during these years.

The celebrated lawsuit which followed failed to place the cause of the epidemic upon the company who raised the dam. Looking at the case from the present standpoint, we should say that some germ carriers, possibly foreigners, as workmen, wandering gipsies and the like, entered the territory around the reservoir, and the conditions being made very favorable by the drought, the mosquitoes became infected in large numbers. Last autumn I had the good fortune to inspect this interesting region both alone and in company with Dr. Adams. Anopheles larvæ were encountered in the ditches in the meadows, in isolated pools and in the river itself. Those which I reared into adults were all *A. punctipennis*.

I have no doubt that similar severe local epidemics have occurred, but they usually fail to find a faithful student and chronicler to put them on record.*

In endeavoring to trace the origin of such localized outbreaks the student of to-day is confronted with the task of searching past records concerning the movement of the population with special reference to the laboring classes. This task, which I have left untouched, would amply repay many a student in searching for subjects for a thesis, and it would utilize the experiments which human beings, quite unaware, have been and are still making upon themselves and upon one another, experiments which are of the highest value as they are inflicted upon us in the natural way.

In the position taken that laborers from malarial countries may introduce intermittent fever, I find myself no longer alone, for similar inferences have been made by European observers recently.

The mouths of the Elbe and the Weser rivers in Germany have been in times past the scene of much work in the construction of wharves, dikes and reclaiming of wet land. Malaria has usually accompanied this work. Martini[53] has recently published an account of several outbreaks which are of special interest to us. A number of Dutch laborers were imported in April, 1901, to work upon a large dike near Wilhelmshafen. Soon after their arrival some were affected with malaria (relapses?). From the scene of their work malaria spread and prevailed in 1901 and 1902.

PROBLEMS OF CLINICAL ANATOMY.[1]

BY THOMAS DWIGHT, M.D., LL.D., BOSTON,

Parkman Professor of Anatomy at the Harvard Medical School.

My attention was called very early in my career, by a murder case in which I figured as an expert, to the fact that all men are not made alike. This started me on my hobby of anatomical variations, concerning which I have had the honor of speaking before this society more than once. Years of observation have taught me that there is a practical clinical side to these studies. Just as the expert hesitates in estimating the height of a body from a single bone, because he is not aware how much the body in question may have varied from the norm, so the practitioner with his patient before him has often wondered whether some uncommon variation of structure might not be the cause of the impossibility of making the symptoms square with what, according to the books, should be the condition of affairs. There is a wide and but little explored area between the domains of anatomy and pathology; a debatable ground passing alternately under the sway of each of the claimants, which contains very valuable mines of information. It is not pure anatomy nor is it pathology. It treats of conditions which for the most part are not recognized during life, but the knowledge of which would have helped the practitioner in many a strait. This knowledge, I may add, is of special importance to the surgeon. The purpose of this paper is to point out certain groups of peculiarities which may be of clinical importance. They include not only variations of structures, but also changes which are the more or less constant results of disease. Increasing knowledge will, I am sure, show us that certain pathological conditions are almost necessarily associated with certain morphological changes. Moreover, the results of certain series of observations are, I think, establishing the law that certain pathological conditions have their origin in some peculiarity of development. Thus certain lesions from trauma occur only when there is an abnormal weakness due to peculiarity of structure. It is worth while to know that certain parts of the skeleton are particularly subject to errors of development, though we may be still ignorant of the cause. Why, for instance, is the last lumbar vertebra the only one in which the arch occasionally, especially in savage races, remains ununited with the body? Or, to take another and more practical instance, for it may affect the motions of the head and be accessible to the x-rays, why are the second and third cervical vertebræ especially likely to be more or less fused, and consequently underdeveloped? Why is the third metatarsal the only one that in the absence of any disease is fused with the tarsal bone supporting it, and why is this fusion limited to the plantar part of the joint? I shall follow none of these topics very far on this occasion, for that calls for minute details which would be out of place to-day. I have, indeed, already written on some of these points and have other papers in the course of preparation and publication. To-day I invite your attention merely to instances illustrating principles. I hope to show that they are of practical importance; nay more, that the deductions from some of them are far-reaching.

As a distinctly clinical point let me call attention to the symptomatology of aneurism of the right subclavian artery. The recurrent laryngeal nerve which winds round it is the chief motor nerve of the right half of the larynx. A certain more or less characteristic paralysis of the muscles of the right half of the larynx is the necessary consequence of an enlargement of the artery at the place where the nerve loops under it. Nevertheless there may be an aneurism at the very place at which it should give rise to this symptom without its appearing. Why? Because in a certain proportion of cases the right subclavian artery, owing to a deviation from the usual course of development, arises the last of the large branches of the arch of the aorta, and passes behind the esophagus to its destination. In these cases the inferior laryngeal nerve is not recurrent, but runs from the vagus in one or two bundles directly to the larynx, having no relation whatever to the subclavian artery. I expect to meet with this arrangement at least once a year, in the dissecting room. Here is a pretty instance of it.

Let us turn to peculiarities which are the direct results of pathological conditions. Look at these specimens of severe Pott's disease. Note how the aorta is as it were half coiled round the spine, lying in transverse folds with sharp angles. These specimens have been already described in print. The stoppage of the circulation by the compression of the vessel at these angles has been given as an explanation of the sudden death that occasionally occurs in this disease. It should be known that this is the most probable course of the aorta under these circumstances.

Here is another and a very different specimen concerning which there might be a good deal of discussion as to whether it is the result of a pathological change or of a congenital malformation. I may not discuss it because an article on it is about to appear in a medical periodical. Let me therefore merely show you this cast of a very remarkable hour-glass stomach which I had the good fortune to find in a hardened body. Plenty of hour-glass stomachs have been shown before now, but the true shape and relations can be learned only when the body has first been hardened. The appearance of this one is, so far as I know, unique. I leave you to judge whether or not such an observation is of clinical importance.

Orthopedic surgery is, perhaps, the most fruitful field of all for this line of research. Let us think for a moment on all the queer positions of the head. Nothing is more characteristic than its poise. I imagine any portrait painter would say that not only are there certain types of head

[1] Read before The Massachusetts Medical Society, June 10, 1903.

and face, but that each of these is associated with some peculiarity in the holding of the head. I do not say that structure determines function; for, beyond question, function modifies structure. Though some positions of the head imply structural peculiarities, certain long-continued postures must have their effect on the original structure. This question is full of difficulties; but what I want to insist upon is that a certain carriage of the head, when once it has become thoroughly habitual, predicates a certain anatomical condition which it imports the practitioner to understand. Which is the cause of the other, and how much one may react on the other, is not clear. Neither is it easy to say when we cross the dividing line between the peculiar and the pathological.

I have here several specimens which I again pass over lightly as I hope to discuss them more thoroughly hereafter. Look at this fusion of the atlas with the occiput. It is symmetrical; the whole of the atlas is developed, only the condyles and the skull are absolutely fused. Was this congenital or acquired? Evidently such a condition must give rise to a peculiarly stiff carriage of the head with, one would think, limitation of the motions. Here is another specimen in which one lateral half of the atlas is underdeveloped and fused with the skull while the other half stands out free. It is a modern skull, which came into my possession only a few years ago. Here is another which would be almost its exact counterpart were it not that the fusion is on the opposite side. It is from a mummy of the twelfth Egyptian dynasty, and at least four thousand years old. Many years ago I bought in Paris the separated bones of a head. Among them was this occipital, which bears on the left a stout process descending from the under side external to the condyle. I was at first at a loss to know what it was, but soon learned that it is known as the *paramastoid process*, which is found in many mammals, and is particularly large in ungulates and rodents. It is common enough in man as an insignificant projection, but this one was remarkable for its size and for being apparently fitted to articulate with the transverse process of the atlas. During the past winter I have found it again, and this time can show you the neck. The paramastoid process rests indeed against a corresponding surface of the transverse process of the atlas. The specimen is from a man of sixty-eight, and again it occurs on the left. Now this condition was evidently congenital. It is self-evident that it must have modified the movements of the head. That it involved a peculiar position is highly probable. Who would have suspected such a condition had the man come as a patient? Had the man been x-rayed would there not have been talk of an exostosis or of a tumor? I must beg leave to omit entirely what is perhaps my best case of peculiar conditions at the junction of the head and neck. I hope within a year to publish all these and others in detail and together.

We come now to some of the most practical considerations connected with this subject. X-ray work has brought a new factor into surgery. Its help can hardly be overestimated; but we must beware that it does not sometimes lead us astray. I do not refer here to the ordinary difficulties in the interpretation of the x-ray negative, of the necessity, for instance, of knowing which side of the object was nearest to the bulb and of allowing for the distance. These and other points are for the expert. I refer to the danger of the misinterpretation of peculiarities of structure. The specimen just shown is a case in point. It is remarkable how little is known of far more common variations. The late Professor Pfitzner wrote of his astonishment at finding that a distinguished surgeon was utterly unaware that the epiphysis which forms the end of the acromion may remain permanently separate from the rest of the bone. Not only would it suggest a fracture under the x-rays, but it might of course be detached by violence that would not break a normal bone. This naturally suggests the burning question of fracture of the scaphoid bone of the wrist, which I think no one had ever heard of before the x-ray. Now it occurs all the time. My friend Dr. Codman was kind enough a while ago to show me a room full of patients with fractured scaphoids at the Massachusetts General Hospital; and yet I still believe that, putting aside extraordinary cases of injury, a normal scaphoid is never broken, and that the separation into two parts, which undoubtedly occurs, is the result of violence acting on a bone composed of two pieces united merely by cartilage. This also I hope before long to establish.

The late lamented Professor Pfitzner of Strasbourg was the true pioneer in the scientific study of the bones of the wrist and ankle. He declined to be limited to the usually accepted number of bones and declared that there are many other true ones, some of which but rarely appear, while others are almost constant in the early cartilaginous stage. Some lose their identity by absolute degeneration, but more commonly this occurs by fusion with one of the neighboring cartilaginous centers. A case in point is what we commonly call the styloid process of the third metacarpal, which projects from the radial side of the base of that bone between the os magnum and the trapezoid in a way that makes the disarticulation of the third metacarpal particularly difficult. Now this styloid process is really a true carpal bone, the *styloid*, which usually, to be sure, joins the metacarpal, but which occasionally joins the os magnum or the trapezoid, thereby considerably modifying the articular lines, or which may indeed persist throughout life as a distinct bone. It is to be noted that such a bone which usually fuses with a certain recognized one, but which exceptionally may fuse with another, is also capable of fusing with both. This accounts for the tendency of particular bones to be fused. At the beginning of this paper I asked why the third metatarsal was particularly likely to be fused with the supporting tarsal bone, and why this always occurs on the plantar side. The answer is: owing to

the existence of a bone of this nature deep in the sole of the foot. Both Pfitzner and I myself have seen this several times in feet which present no sign of any pathological process. I have a specimen of it in a beautifully formed foot of a girl of nineteen.

Now it is evident that the persistence of such an occasional bone may give rise to x-ray negatives that are liable to misinterpretation. Many years ago, before the x-rays had been thought of, an excellent anatomist and surgeon thought that he had found in the dissecting room a fracture of the astragalus, because the external tubercle at the back of the astragalus was distinct. This is now known as the *os trigonum*, which may be found in all degrees of fusion, from complete distinctness to absolute incorporation with the astragalus. No one knows how many of these distinct centers of the wrist and ankle there may still be to discover. I had the luck a year or more ago to find a new bone in the ankle (the *os intercuneiforme*), and I think I have found a new one this winter in the wrist. To be sure, these discoveries at first may seem of no more value than that of one more asteroid or of a one-horse comet, which nevertheless are telegraphed all over the world; but I am sure that many of them have their very practical significance. Conversely the fusion of bones usually distinct is of practical importance. I have just mentioned one way in which it occurs, but it is not likely that it is the only one. Fusion of distinct bones is not only a disturbing circumstance to the operator who expects to sweep his knife gracefully between them, but it is of greater importance to the orthopedist who is studying the relations between structure and, let us say, flat foot. Thus the os calcis occasionally is connected by cartilage or fibro-cartilage with the outer end of the scaphoid. Though I believe the opposite opinion has been maintained, I think from my experience that it is associated with a high instep. What influence it may have on the movements of the foot is a more abstruse problem.

And so on, and so on:

> "Though I'm anything but clever,
> I could talk like this forever,"

and keep on showing you peculiarities which once were (perhaps still are) considered mere curiosities, but which in point of fact are alike of great scientific and of great practical importance. Let no one say that anatomy is exhausted. On the contrary, we are just entering on a new era, and on one which concerns especially the practitioner who would be eminent.

THE NEED OF A SUPPLEMENTARY LANTERN TEST FOR THE PROPER EXAMINATION OF COLOR PERCEPTION.[1]

BY CHARLES H. WILLIAMS, M.D., BOSTON, MASS.

THE test for color vision most commonly used at present is that proposed by Professor Holmgren. It consists of a collection of skeins of worsted of various colors, one hundred and twenty-five or more in number, well provided with different shades of red, green, blue, brown, gray and other colors. In addition to these there are two or three larger test-skeins, one of green, one of rose and one of bright red, the last being omitted in some of the test sets.

The principle on which this test is based is the fact that when a person who has a decided lack of perception for red or green looks at the solar spectrum, he sees in the green part of the spectrum a band of gray or neutral color, and this green test skein is carefully selected so as to correspond to that part of the green spectrum where the gray band is seen. To a person who is defective either for red or green, this green test-skein will appear of the same color as the light grays, or browns, and he will select as looking like it other grays, greens or browns, and will show by this mixing of confusion colors with the true colors that he is defective in his color perception, either for red or green, or both of these colors. The second test is made by placing a rose test-skein at one side of the pile of worsteds and having the person examined select such colors as look to him like this test-skein. If he is more defective for red, he will select with the rose or reds some of the blues or violets; but if he is more defective for green he will select with the rose some of the grays or greens. The green test-skein, which has generally been furnished with our American sets of worsteds, has been too light in shade, and on comparing it with the green test-skein in some sets of Holmgren worsteds imported from Upsala by the writer, and which were prepared by the person who made them under the direction of the late Professor Holmgren, it was found that the green test-skein of the Swedish sets was much darker and of a more decided green than ours, and was better adapted for use as a test-skein; and in some of the American sets of worsteds now made this defect has been corrected.

Some ten years ago the writer prepared fifty sets of Holmgren worsteds for use on the Burlington system of railways. In these sets all the skeins were numbered with small metal tags, the odd numbers being the true colors and the even numbers the confusion colors. By making a record of each examination as it proceeded, noting on proper blanks the numbers selected as looking like the test-skeins, a permanent record was kept of all examinations, which was sometimes of great use. Formerly the only record of the examination was the statement of the examiner who conducted the examination, as to whether the applicant's color vision was satisfactory or not.

A very extended use of the Holmgren test in the hands of many examiners is now showing that some cases are able to pass this test correctly and without hesitation, who when examined with the lights from a distant signal, may be unable to distinguish the red or green with any reasonable degree of certainty, and, in fact,

[1] Read at the Medical Meeting of the Boston Medical Library, April 6, 1903.

often confuse these colors. This occurs most frequently in cases of acquired defect in color-vision caused by excessive use of tobacco or alcohol, or by a combination of the two. In such cases there is often a small defect in the central part of the retina, so small that the retinal image of the skein of worsted is large enough to be formed partly within the affected area and partly beyond it, and if at any part it falls on healthy retina its color can be at once recognized. If the object is small, like a distant signal light, the retinal image is formed wholly within the affected area, and the color is not recognized. At night there is often no other means of distinguishing between safety and danger except by the quick and accurate recognition of the color of a railway signal or the side light of a ship, and it is of special importance that the test for color perception should include a test resembling as nearly as possible the conditions of service, and of such a kind as to show conclusively, after the test has been made, whether the person can be relied on to recognize quickly and accurately the color of a distant signal light. For some years the Dutch railways have required a test with the Donders lantern, in addition to the worsted test, but my experience with this lantern showed that it was not well adapted to tests made by railway officials, as is often done in this country.

In 1892 the writer devised a wheel with sixteen colored glasses, which could be brought in succession before a light by revolving the wheel; there was also a diaphragm to vary the size of the colored area, and this test is still used as a reference test on the Burlington road. In 1899 a smaller and more portable lantern was arranged for use on the N. Y., N. H. & H. R. R., when they revised the methods of examining their men

This lantern showed only one light at a time, and was soon replaced by another in which either one or two lights could be shown at a time, and where the colors of the glasses in the lower disc could be modified by combinations with the glasses of the upper disc, and where the area of the colors could be varied.

This lantern is now in use on the N.Y., N. H. & H. R. R., the Great Northern, the Boston & Maine, the Canada Atlantic and some other roads. It has been found in practice that the

MODEL OF 1903.

upper disc of these lanterns is seldom used, and it brings in a complication which is not desirable. It is very necessary that these tests should be made as simple as possible, so that a person of good intelligence can be easily instructed to make them in such a way as to give reliable results, especially when they have printed instructions and forms to guide them. For this reason a new lantern was constructed this year having on its face a single disc with eighteen colored glasses, and within the lantern two lights and a shutter, so arranged that either two or one of the colored glasses can be illuminated at one time. By revolving the disc all the colors can be brought before the lights in succession, and it is found that with two lights showing at one time, a person with defective color-perception is often more confused than when he has only one colored light to look at; for instance, with a light and a dark red he will often call one of them a green and the other a red. The shutter, beside regulating the lights as single or double, also changes the area, so that two lights with the full opening, half size, or the smallest opening can be shown, or one light of each of these sizes. Under each colored glass in the disc is an opening with a transparent number, which is lighted at the same time as the color above it. This number can be seen by the examiner, but is screened from the person examined, and by means of these numbers a record of the examination can be kept, the number under the color and the name given to this color being noted as the examination proceeds. The lantern is placed in a dark room twenty feet from the person to be examined, and on a level with his head. The area of the largest opening at this distance then corresponds to the apparent size of a standard switch light at a distance of 160 feet, and the smallest opening to such a light at a distance of 1,300 feet.

This form of lantern is already in use on the Canadian Pacific Railway and the Northern Pacific Railway, and is to be preferred, on account of its greater simplicity, to the previous models.[1] In addition to the test with different colored lights, it is important to make the test with a light whose intensity can be varied by fixed amounts; for in some cases those who are defective depend on the intensity of the light to distinguish between red and green. For this purpose the writer made an electric lamp with a specially constructed rheostat in the base, through which the current for the two incandescent lamps can be passed.

[1] Since this paper was written, twenty of these lanterns have been ordered for use on the different divisions of the Southern Pacific Co.

By means of a handle projecting through the door at the back of the lantern the resistance introduced by the rheostat into the current for the lamps can be varied from nothing to 150 ohms, and the candle power of the lamps can thus be reduced or raised by fixed amounts at pleasure. Oil lamps are used in case an electric current cannot be obtained, but the latter is preferred. This lantern test is now used on the above roads *in addition to* the Holmgren worsted test. If a person calls red green, or green red, in the lantern test, or selects confusion colors with both the green and the rose test-skeins, he is rejected as showing an unsafe degree of defective color-perception.

With these two tests carefully made it is reasonably certain that no dangerous case of defective color-sense will be passed; but with either test alone it is possible to have men pass the test who are so defective that they may be dangerous in positions where it is necessary to distinguish quickly and accurately between red and green. In cases where the trouble is due to an acquired defect, as from the excessive use of tobacco, a considerable improvement may result from stopping the tobacco; but in the congenital cases no treatment will be of much use. Some men can learn by constant practice to give the correct names to certain colors or even to select correctly the proper colors in a given set of worsteds, but when tested with new colors that they have not previously seen and practiced with, they will generally be unable to recognize them correctly.

EFFORTS TO ABATE THE MOSQUITO NUISANCE IN BROOKLINE.

BY H. LINCOLN CHASE, M.D., BROOKLINE, MASS.

THE great prevalence of mosquitoes every spring, summer and fall in certain sections of Brookline, the increasing number of citizens in every part of the town, the comparatively recent discovery that intermittent fever is transmitted from a patient to well persons through the bite of a mosquito,— these facts induced the Board of Health in August, 1901, to consider the feasibility of suppressing the mosquito nuisance.

The Board of Health voted to refer the matter to its agent, the writer, for an investigation and report, with recommendations. The report was duly made, and summarized most of the information then available on the subject, much of which was secured from Dr. Theobald Smith's valuable and interesting paper on the subject given before the Massachusetts Association of Boards of Health at its meeting in July, 1901; partly from Dr. L. O. Howard's book entitled "Mosquitoes" and much also from the experience of our medical officers in Cuba in suppressing the mosquitoes that transmit malaria and yellow fever. The Board promptly authorized its agent

to proceed along the lines recommended in his report.

We prepared a list, with the help of our Police Department, of nearly all the stagnant water in the town. We next marked the exact location of all these places on the town map, and had them systematically inspected and reported on by Mr. Nyhen, the Board of Health laboratory assistant, as to the presence or absence of mosquito larvæ, and of their natural enemies, frogs and fish.

An examination was also made of a number of our street catch-basins; and, with the exception of those few that received large quantities of cold water from neighboring standpipes, all were found to be teeming with mosquito larvæ, all of which were those of culex. Our largest body of water, Leverett Pond, was found at that time to be entirely free from larvæ, minnows and other fish being quite plentiful. Other ponds that had either no larvæ visible, or only very small ones, were found to be well supplied with frogs. Most of the ponds, pools and ditches, however, were found to be breeding places of mosquitoes, all furnishing larvæ of culex in abundance; and quite a number, notably those off upper Boylston Street, near Chestnut Hill, where malaria has been more or less prevalent for some years, had numerous larvæ of anopheles.

We secured a barrel of light fuel oil, and in September Mr. Nyhen, with the help of a laborer and a horse and wagon, treated a single time all of the breeding places of anopheles and all the more important breeding places of culex in the more thickly settled sections of the town, including two hundred and fifty catch-basins. Every pond surface was measured more or less accurately. Light fuel oil was then applied, and the surface of the water well agitated with a pole to hasten the diffusion of the oil. As an experiment we also put quicklime into a few shallow pools, but were rather disappointed in the results. Later we filled in all shallow pools. The oil treatment we found very successful as a temporary measure, especially in the catch-basins, all of which, almost three weeks after treatment, remained wholly free from larvæ.

At the same time that we began to treat the larger breeding places of mosquitoes, we distributed by the police to each family in town the following circular of information:

OFFICE OF THE BOARD OF HEALTH,
BROOKLINE, MASS., Sept. 9, 1901.

MOSQUITOES.

Both malarial and common mosquitoes are numerous in Brookline, and the Board of Health invites the co-operation of citizens in its efforts to diminish their numbers and to reduce the areas in which they breed.

Mosquitoes always lay their eggs in water, as the young (larvæ) cannot live elsewhere. They rarely fly far, and their presence is usually accounted for by the existence of standing water close at hand. The eggs and larvæ abound throughout the season in ponds, pools, puddles, cisterns, rain barrels, water buckets, old tin cans, clogged gutters, and, in fact, everywhere where even a very little water is allowed to stand for a few days.

Experience in other places has shown that much good can be accomplished by giving attention to all the standing water in any neighborhood. In permanent ponds, fish and frogs, if in sufficient numbers, will destroy the eggs and larvæ, but care is needed to see that small pools around the edges are filled up or treated with oil. Unnecessary pools and puddles of all kinds should be drained or filled up. A little kerosene oil (preferably "light fuel oil") put into standing water spreads easily and rapidly over the surface, and, without injuring the water for other purposes, destroys the larvæ, and prevents the laying of eggs. An ounce of oil is sufficient for fifteen square feet of surface; and an application of it is effective for about two weeks, at the end of which time it should be renewed. Good results have also been obtained by putting unslaked lime into standing water.

The mosquitoes which live through the winter in cellars and barns, under bridges, and in other sheltered places, lay eggs again in the following spring; and it is believed that active measures taken now will materially reduce the numbers to survive the winter. The board intends to treat some of the worst places in town with oil at once, and to remove certain stagnant water entirely, and also to follow the matter up closely early next year. Citizens are urged to look after all standing water on their own premises.

OUTFIT OF 1891.

Mr. Nyhen was given the personal supervision of the work in the field, under the direction of the agent of the board. He was allowed one laborer at $1.75 per day to assist him. Our equipment consisted of: One hired horse and light wagon; 1 outfit for collecting specimens of larvæ, pupæ and adult mosquitoes; 1 five-gallon oil can; 1 single gallon watering-pot; 1 brass spigot; 2 galvanized iron oil dripping pans; 1 pick; 1 funnel; 50 gallons light fuel oil.

Beginning the work in September, we hoped to destroy the last mosquito larvæ of the season, the ones that otherwise would have matured and lived through the winter, to produce the first brood of mosquitoes of the following spring. So much for the season of 1901.

Early in 1902 the board allowed four hundred dollars for mosquito work, and those in charge prepared to make an early start. For various reasons, however, work could not be begun until early in May; while the mosquitoes appeared in considerable force late in April.

A second circular of information, more particularly in regard to the cause and prevention of malarial fever, was prepared, and distributed by the police to every family in town. In response to the request to the citizens to report all probable breeding places known to them, numbers of notifications were received,

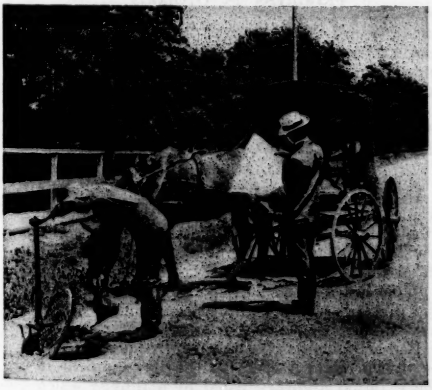
Mr. Nyhen was placed in immediate charge of the work as previously, and most of the season he had at his disposal two laborers at $1.75 each per day, and a horse and wagon. The equipment consisted of most of that of 1901, and in addition we had the following list of articles: Four five-gallon oil cans; 1 ten-gallon oil can; 2 picks; 2 hoes; 2 rakes; 2 shovels; 2 scythes; 2 Breck hand-force pumps; 3 one-gallon watering-pots; 16 feet of hose in three sections; 3 galvanized iron pails; 2 pairs of deep water leather boots, for use by men handling oil; 3 pairs of deep water rubber boots; 1 zinc wagon pan; 500 gallons of light fuel oil.

This outfit proved to be somewhat inadequate, but the tools and utensils used were as suitable

as could be found. More satisfactory tools might be devised. We badly needed two or three more laborers.

METHODS OF WORK.

(1) All pools, ponds, ditches and other breeding places, including catch-basins, were located upon the town map. We also located and treated a number of breeding places just beyond the town's borders.



(2) The approximate areas were determined, and the number of catch-basins ascertained.

(3) Breeding places of culex and anopheles, respectively, were determined, and also the places where both species were breeding. This we did in order to learn the proper intervals for treatment; that is, whether every three weeks or every four weeks.

(4) The location on the town map of the public dumps or other places where accidental receptacles of water were to be found ; for example, tin cans and boxes.

(5) Details of treatment, temporary or permanent. Petrolizing, and necessary work preliminary to it. Last, but most important of all, filling or draining.

Treatment of catch-basins. — Three ounces of light fuel oil we found to be the necessary quantity for each treatment of one of our street catch-basins. This will keep the catch-basin free from larvæ, and prevent mosquitoes from laying their eggs, for a period of about three weeks.

TREATMENT OF A CATCH-BASIN.

The treatment of ponds and ditches. — The amount of oil used for a given pool or pond we determined as follows: Calculate the amount necessary from Dr. Howard's rule, 1 oz. of light fuel oil to fifteen square feet. If the pond had vegetation growing luxuriantly in it, irregular shores, and a large amount of vegetation about it, we added an excess of one fourth of the original amount. If the pool presented a clear water surface, we added one sixth more than the usual amount. Pools well stocked with fish did not require a film of oil over the entire surface; but

"PETROLIZING" AND "PUDDLING."

a belt about fifteen feet in width, extending around the shores, was thoroughly treated.

If a pool or pond had fish or frogs in it, we examined it very carefully until we were satisfied that it was not a mosquito breeding pool; for we found a number of ponds well stocked with fish and frogs that were, nevertheless, breeding places of culex and anopheles. We found that the film of light fuel oil did not kill either fish or frogs.

In treating ditches the amount of oil was calculated and distributed as evenly as possible; and, if necessary, the water was well agitated.

After the oil had been evenly spread upon the pond from the most favorable working points, a man styled the "puddler" violently agitated the

"PUDDLING."

water with a hoe. These photographs, kindly taken for us by Dr. Walter G. Chase, show very faithfully some breeding places of mosquitoes and our methods of treatment.

The treatment of pools, ponds and ditches where rank vegetation was abundant was begun by removing this vegetation with scythes as completely as possible for the distance of about fifteen feet from the edge of the pool to be treated. The shallow pools, if not large in area, we filled in. If a pool stood near a dump, we gathered into it accidental receptacles and covered them with sufficient soil. We drained or filled in a great many small pools.

Accidental receptacles. — We found on our public and private dumping places a great many small receptacles of water which proved to be important breeding places of mosquitoes, especially for anopheles. We gathered all metal receptacles that would hold water, and either used

them in filling up pools or buried them. Bottles and wooden receptacles we simply broke up.

Of course petrolizing is but a temporary expedient; only draining or filling in can result in a permanent removal of a mosquito breeding place. To this end the board directed Mr. Alexis H. French, the town engineer, to examine and report upon, with reference to their drainage, several sections of swamp land, and to furnish an estimate of the probable cost of the drainage. In this connection the following letter from Dr. Abbott, secretary of the State Board of Health, is of interest:

BOSTON, May 22, 1902.

DR. H. L. CHASE,
Agent Board of Health, Brookline:

Dear Doctor: — In reply to your further inquiry, on behalf of your board, there can be no doubt that wet lands and stagnant bodies of water constitute a serious nuisance, especially in thickly settled towns, since, when the question is considered both subjectively and objectively, the presence of human beings is essential to the existence of a nuisance. Wet lands in uninhabitated districts are of course not dangerous, because there are no human beings to whom they may prove harmful; but in large towns the case is necessarily otherwise.

The statutes (Revised Laws, Chap. 75, §75) already provide that "land which is wet, rotten, or spongy or covered with stagnant water, so that it is offensive to residents in its vicinity or injurious to health, shall be deemed a nuisance"; and the recent discoveries relating to the dangerous nature of insects bred in such places only strengthen the statement expressed in the statutes.

Yours respectfully,
SAMUEL W. ABBOTT,
Secretary.

The final treatment for the season of all the catch-basins and other breeding places was given during the month of September.

RESULTS.

Our work had not been going on more than a month when many citizens noted and favorably commented on the marked diminution in the number of mosquitoes in the formerly infested districts, especially the Longwood district. The work went steadily on; and the results were such that the Board of Health increased the mosquito working force from one laborer to two, and provided a little more money. So great an improvement was noticed in every district that letters of commendation from many representative citizens were received, some of them from physicans.

The most important object of this work — namely, the prevention of malarial fever — should not be overlooked. In December, 1897, the agent of the board wrote to most of the practising physicians of the town, requesting each to report to him, as a favor, the number and location of his malarial fever cases, of tertian type only, seen by him during the previous season. The total number of typical cases reported was not less than fifty. Since May, 1902, the Board of Health has required the reporting of every new case of malarial fever, and received notice last year of only twelve cases.

The writer regrets that the latter part of the past season was unusually cool, thus making a test of the work less severe than during the earlier part of the season.

The total cost of this work, up to the middle of September, in addition to the loss of time involved in its supervision, was $625.57.

In our work we had assistance from our bacteriologist, Dr. Francis P. Denny, our town engineer, our superintendent of streets, our park commissioners and some other town officers.

For the work of the present mosquito season (1903) the sum of one thousand dollars has been appropriated, but the work will not be conducted in all respects as it was last year. By direction of the Board of Health, the owners of mosquito breeding lands have been sent letters informing them as to what should be done in order to abate the nuisance, and inquiring whether they are able and willing to undertake the work. The Street Department and the Park Department have received orders to attend to all street catch-basins, public dumping places, pools and ditches on the town lands throughout the season.

The board will decide later what it will do where land owners, for any reason, do not prevent mosquito breeding on their premises; it is possible that it may return to the policy which last season proved very satisfactory in its practical results.

Medical Progress.

PROGRESS IN OTOLOGY.

BY PHILIP HAMMOND, M.D., BOSTON.

ARLT [1] reports good results in cases of malformation of the auricle by the subcutaneous injection of small quantities of paraffin.

Where the auricles are unduly prominent, Pooly [2] advises operation, using cocaine anesthesia.

EXTERNAL AUDITORY CANAL.

In otitis externa, Randolph [3] obtains the best results by filling the canal with a strong solution of nitrate of silver (gr. 30 to the ounce). This usually stops the intolerable itching of which the patients complain.

Wheelock [4] reports a discharge of blood through the intact external auditory canal in a case of hystero-epilepsy.

Red cerumen has been shown by Pacinotti [5] to be due in certain cases to the development in the external auditory canal of a fungus which he identifies as Oospora constacea, or Monilia miniata.

BACTERIOLOGY.

Phillips [6] states that a search of the literature of the subject reveals the fact that some twenty odd distinct kinds of bacteria have been observed in the discharge from purulent ears.

[1] Monatschr. f. Ohrenh., September, 1901.
[2] N. Y. Med. Journ., July 13, 1902.
[3] Progress. Med., March, 1903.
[4] Amer. Med., Aug. 3, 1901.
[5] La Semaine Médicale, Nov. 13, 1901.
[6] Trans. Am. Laryng., Rhin. and Otolog. Soc., 1902.

Bacteriologic examination of the discharge is now considered to be a most important aid in diagnosis and also prognosis, but it is important that the culture be taken as early in the case as possible. Unless we examine immediately after opening the membrana tympani, we cannot be sure that the organism did not enter the ear from without. There is no specific germ of otitis media, nor is the disease invariably mono-microbic.

Funk [7] is responsible for the statement that the organisms found in the frequency of their occurrence are pneumococci, streptococci, staphylococci, Friedlander's bacillus and diphtheria. He also points out that it is almost impossible to demonstrate the presence of the tubercle bacillus in the discharge from the ear, and recommends that bits of tissue removed by the curette be examined for organisms.

Albesheim,[8] in a study of otitis media occurring during measles, found streptococcus once in pure culture; once the staphylococcus albus. In two other cases each of these bacteria was seen in conjunction with a bacillus which could not be identified.

Grimmer [9] has succeeded in inoculating guinea pigs with tuberculosis from material obtained from the granulations of suppurative ears. He considers that intra-peritoneal injections in this manner are a most conclusive proof of the presence or absence of tuberculosis. He also states that the presence of cholesteatomatous material is positively opposed to tubercles being present.

Trow [10] claims that tuberculosis of the ear may be acute or chronic. In the acute stages there is general diffuse cellular infiltration of the mucous membrane and proliferation of the cellular elements; there are few, if any, giant cells, but a large number of tubercle bacilli. The mucous membrane breaks down rapidly, with resulting great loss of substance. In the chronic form bacilli are not abundant, the mucous membrane has a tendency to granulate, and under favorable circumstances connective tissue may form, with healing as an ultimate result. It occurs much more frequently as a secondary infection than as primary, and generally takes place through the Eustachian tube. It is often insidious, sometimes occurring without rupture of the drum membrane, and without pain. As regards treatment other than general, it is of the utmost importance to keep the ear as dry and free from discharge as possible.

Goldstein [6] firmly believes in the existence of primary tubercular infection of the ear, and quotes an exhaustive bibliography to substantiate his opinion that it is not only possible, but extremely likely, that it is more frequent than a first consideration of the subject would indicate. Four cases are reported in support of the author's views, in which positive microscopic evidence was obtained.

HEARING TESTS.

Andrews [11] calls attention to the possible sources of error in testing the hearing. They may arise from poorly adapted or imperfectly understood instruments, or the fault may lie with the examiner, or from the failure of the patient to promptly and accurately respond to the various tests. Although there are many tuning forks on the market, there are few or none absolutely free from defects. The advantage possessed by the weighted forks, rendering them free from overtones, becomes positively detrimental when they are applied to the bone, because of the jarring sensation transmitted through the handle. A very important objection to the use of the ordinary fork is the length of time during which its vibration may be heard. In making repeated tests for the sake of accuracy, not only is much unnecessary time wasted where the fork vibrates more than a minute, but the patient easily becomes tired, and does not respond readily to the tests. Many of the published records of hearings are absolutely valueless, because of the neglect to specify the length of time during which the normal ear could hear the fork in question.

Attention is called to the intimate relation existing between a diseased nose and audition by Crouch,[12] who reports two cases of unilateral deafness accompanied by suppurating maxillary antrum, which resisted all ordinary methods of treatment, but were permanently cured by relieving the sinus trouble.

MEMBRANA TYMPANI.

According to Lucae,[13] the artificial drum does not act by increasing labyrinthine pressure, for in this case to obtain the desired effect it should always be placed against one of the two windows, whereas he has always been able to secure good results by placing it against the upper portion of the promontory.

Gomperz[14] does not believe in the value of the artificial drum unless there is destruction of more than one quarter of the membrane. He has, however, observed patients who complained of buzzing in the ear and of a feeling of heaviness in the head improve markedly by the application of the artificial support. He has been in the habit of employing for this purpose a drum made of pure silver molded into the proper shape.

In the case of large perforations Bentzen[15] has used a tampon made of cotton, shaped like a ball. This he presses up against the round window, obtaining the best results from this location.

To close old perforations of the drum, Gomperz [14] applies trichloracetic acid on a cotton stick to the edges. This method is somewhat

[11] Laryngoscope, April, 1902.
[12] Journ. of Eye, Ear, Nose and Throat Dis., January–February, 1902.
[13] Archiv f. Ohrenh., Bd. liv, H. 3 u. 4.
[14] Ann. des Malad. de l'Oreille, du Larynx, etc., October, 1902.
[15] Monatsch. f. Ohrenh., January, 1902.

painful, but seems free from danger. He considers that the treatment is indicated in all kinds of perforations.

Randolph [3] strongly urges the importance of an early incision of the drum membrane in cases of acute inflammation, as does also Meierhof.[16] The latter regards it a safe rule to puncture when in doubt, especially in the acute exanthemata. Delay means breaking down of the tissue, perforation and a more or less lengthy siege of otorrhea.

Körner [17] presents a table of statistics regarding paracentesis of the drum membrane, which shows conclusively that the earlier the incision is made in the drum the earlier the recovery. There seems to be no doubt that the best safeguard against mastoiditis is a prompt opening of the drum.

Frost [18] mentions a case in which erysipelas spread from the throat through the Eustachian tube and middle ear to the face.

FACIAL PARALYSIS.

Harvey Cushing [19] has succeeded in re-establishing the function of the facial nerve after it had been completely severed by a bullet wound in the mastoid region. Six weeks after the injury, and after the mastoid wound had completely healed, Cushing severed the spinal accessory and united it with the facial. Six months later the patient had very fair control of the facial muscles, with the characteristic droop of the shoulder seen in cases of an injury to the accessory nerve.

This opens a most promising field of surgery for the relief of some of our most disfiguring cases, and one of which we will undoubtedly hear more within the next year or two. Already Ballance and Stewart[20] have reported cases in which practically the same operation was done, the patient being subsequently treated by electricity. The results have been most encouraging.

Reik [21] has considered the etiology of paralysis of the facial, which, although not dangerous, is a most disagreeable symptom, and has long been recognized as a complication of ear diseases. It may, however, occur with so slight a disturbance in the ear that the latter is scarcely perceptible. Such an instance is reported by Reik, who sums up the points in his paper as follows:

(1) If exposure to cold in one way or another is the cause of most cases of facial paralysis, it probably acts most commonly through the production of an otitis media, whereby the nerve becomes involved either in a direct extension of the inflammatory process to its exposed sheath, or through pressure upon it of an exudate.

(2) This being admitted, the form of treatment which offers the most rapid and satisfactory results is a paracentesis of the tympanic membrane to free the cavity of its abnormal contents.

(3) We should never, in any case of facial paralysis, neglect to examine the ear.

SUPPURATIVE INFLAMMATIONS OF THE MIDDLE EAR.

In a consideration of the cause of purulent inflammations of the middle ear, Kuhnlein [22] found that in the summer months, when nasopharyngeal troubles were less prevalent, there were fewer cases of ear involvement.

Urbantschitsch [23] reports two cases where there was a small amount of muco-purulent discharge from the ear at regular intervals, which seemed to entirely recover as a result of inhalations of nitrite of amyl. He thinks the condition was evidently a tropho-neurosis.

Muller [13] reports ten cases of chronic suppuration with various neuroses, such as epilepsy, chorea, etc., in which there was marked improvement of the nervous condition following a radical operation and cure of the otorrhea. The dura was freely exposed in all the operations, and Muller ascribes the amelioration of the symptoms to changes in the blood supply of this protective membrane.

The question of the influence of syphilis as a cause of inflammations of the ear is discussed by Parmentier,[24] who records the case of a woman who had an otorrhea of six months' duration, and on examination was found to have a large polyp springing from a perforation located at the superior and posterior portion of the tympanic membrane. In addition to this there were clinical manifestations of secondary syphilis. The patient refused to have the polyp removed, and was placed upon anti-syphilitic treatment. At the end of two months, during which this treatment was continued, the discharge had entirely stopped, the polyp had disappeared, and in its place was found a beautiful cicatrix of the drum membrane. Parmentier regards the aural trouble as distinctly one of syphilitic origin.

Grunert [25] cites two cases of otitis in which examinations of the urine previously made showed no sugar to be present, while during the height of the disease large amounts of sugar were excreted in spite of the fact that all carbohydrates were withdrawn from the food. Both were cases of chronic suppuration. One was complicated by a diffuse purulent meningitis, as was proven by lumbar puncture. In the other there was an extradural abscess. Operative measures were employed in both cases, and after recovery the urine was found free from sugar, although a mixed diet was given. One of the cases was under observation for nearly five months, and during that time the urine was always free from sugar.

[25] Arch. f. Ohrenh., Bd. lv, H. 3 u. 4.

Richards [6] points out that one of the chief reasons for the existence of cases of chronic suppuration is the fact that many general practitioners do not yet appreciate the dangers which arise from the presence of pus in the ear. He advocates operation in cases which do not improve within a reasonable length of time, and emphasizes the danger of the formation of brain abscess. The possible influence of the operative measures upon the hearing power should not be reckoned a factor in these cases; the danger to the life of the individual is more to be considered than any possible loss of hearing as a result of operative interference.

That this danger is a well-recognized one was noted by the writer [26] in an article showing the importance of certain diseases of the ear with reference to life insurance.

Dench [6] finds that intra-tympanic caries is the underlying cause of nearly all cases of chronic discharge, and believes that we must treat the cases surgically just as we would handle a similar condition with dead bone in any other portion of the body. There are two methods of procedure open to the operator: First, the removal of all dead bone through the external auditory canal; second, where the disease is extensive, we can accomplish our purpose only by removing the bony walls enclosing the ear cavity. In the early stages intra-tympanic caries is confined to the ossicles, and their removal is sufficient to constitute a cure. Superficial caries of the tympanum, even, may be removed in this way. The operation is an ideal one, and confines the patient to the house for only a few days. It is absolutely essential that the incus be removed.

Pearce [6] has tried removal of the ossicles in some cases under a local anesthetic, but has lately always resorted to ether. In cases of granulation tissue, bleeding may interfere with the different steps of the operation to such an extent that the patient's endurance may be exhausted, and it may become impossible to complete the operation.

Packard [6] observed a case of necrosis of the temporal bone following scarlet fever in a boy of four and a half years. The discharge had existed for a few weeks only, and when seen, there was a large sequestrum filling the left auditory meatus.

Fougeray [27] has for the past eight years been using medicated gauze for tamponing the canal in cases of otitis media suppurativa. Originally he experimented with iodoform gauze, but of recent years he has been obtaining his best results from the use of naphtholated crinoline gauze. His technique consists in cleaning out the canal, filling it with hydrogen peroxide, and without allowing this to run out, to tampon the canal with gauze.

Bezold [28] is absolutely opposed to the tamponing of the canal with gauze under any circumstances in cases of suppuration. He has been accustomed to filling the meatus with boracic acid powder, but this method seems to be open to the objection that the powder readily forms hard masses, blocking the drainage.

Gautier [29] has experimented with methylene blue as an antiseptic in the treatment of chronic otorrhea, particularly where there was much odor. His method was to first wash out the external auditory canal, and then instill fifteen or twenty drops of a lukewarm solution of 1:500 methylene blue. This was allowed to remain in the ear for five minutes. A serious objection to its use, however, was the difficulty of avoiding the staining of the face and parts adjacent to the ear.

Snydacker [30] has reported the results obtained from a microscopic examination of the discharge in chronic suppuration. He considers the presence of shreds of epidermis or of bone dust to be of more value as a diagnostic point than a bacteriological finding.

To facilitate the removal of large polypi, Bellevue [31] is accustomed to inject into the substance of the growth 1 cc. of a 5% solution of cocaine. This spreads throughout the tumor, including its attachment, and apparently gives rise to no trouble from absorption, as most of the solution is removed with the polyp.

As the result of histological examinations, Bruhl [32] found that out of 60 aural polypi 47 were polypoid granulations, 8 were fibromas and 5 myxo-fibromas.

Reports of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

TWENTY-FIFTH ANNUAL MEETING, WASHINGTON, D. C., MAY 12, 13 AND 14, 1903

FIRST DAY. — TUESDAY, MAY 12.

SOME CASES OF CANCER TREATED BY THE X-RAY.

DR. ARTHUR H. BLISS of Philadelphia read the above paper, being a report of two cases and comments on the method of treatment.

One case involved the ethmoid and sphenoid regions, both orbits and eyelids. Syphilis was excluded from the history, and a pathological examination showed the growth to be carcinoma. One operation had been done, clearing out the ethmoid and frontal region on the right side and taking out the right eye. The x-rays were used late in the case, with treatments three times a week for about five minutes at a sitting. The other case gave a history of syphilis twenty years previous; the growth was in the tongue, and the lymph nodes of the neck were enlarged and the floor of the mouth in-

filtrated. Potassium iodide had no effect on the growth, and although no pathological examination had been made, the clinical aspect of the case was one of carcinoma. The x-rays were used as in the previous case. There was some slight improvement at first, with less rapid growth at the periphery of the mass, and a moderate degree of relief from pain; but no effect upon the mass of the tumor.

The author's conclusions were that no permanent improvement or cure was to be expected in these cases, although the x-ray was undoubtedly valuable in the treatment of purely superficial lesions, such as lupus; and that in such cases of deep involvement, early radical operation was indicated, and that valuable time should not be lost in the use of the x-ray.

DR. DELEVAN of New York, in discussing the paper, said that he agreed with the negative conclusions of the author; and reaffirmed his own conclusions, as stated in his own paper of a year ago, that no authentic case was yet on record of any permanent good results from x-ray treatment in deep-seated growths. He said he thought it might possibly do some good if used very early; but if no good resulted promptly it should not be continued so long as to allow the growth to get beyond legitimate radical operation.

DR. GLEITSMANN of New York, DR. SWAIN of New Haven, DR. COOLIDGE of Boston, DR. BIRKETT of Montreal and DR. SIMPSON of New York, all confirmed from their own experience the negative results from the use of x-rays in cases of deep-seated growths.

SOME FURTHER INVESTIGATIONS OF THE CHEMICAL PATHOLOGY OF THE SALIVA.

DR. D. BRADEN KYLE of Philadelphia read this paper. He detailed many laboratory and clinical experiments and observations of the changes in the character of the saliva, under different conditions of diet, hygiene, climate and medication, and spoke particularly of the frequent evolution of irritating substances, often gases, and their influence upon conditions of hay fever, either as causative or aggravating factors. He claimed that some cases of hay fever were directly caused by this irritating condition of the saliva, and could be properly treated only by changing the character of that secretion.

ADENOID VEGETATIONS, WITH SPECIAL REFERENCE TO ADULT CONDITIONS.

DR. JAMES E. LOGAN of Kansas City called attention to the importance, in all acute infectious diseases, of a careful examination of the naso-pharynx, and the thorough antiseptic cleansing thereof. He thought that neglect of adenoids in the adult was responsible for the frequent failure in the treatment of obstinate cases of affections of the middle ear and upper air passages. The author, though finding little reference in literature to adenoids in the adult, a fact suggesting either rarity or small importance of the condition, said that in his experience this was not so, and as illustrating the importance of the condition, mentioned a case of complete deafness, excepting by bony conduction, in which the naso-pharynx was full of adenoids and both nostrils obstructed by hypertrophied turbinates, in which full hearing was recovered after the nose and naso-pharynx were cleared out.

As to the presence of adenoids in the adult, he quoted Raulin of Marseilles, and agreed with his conclusions, that when present they usually dated from childhood, not being developed after puberty when absent previously; and that when present they usually caused deafness, or chronic nasal or naso-pharyngeal catarrh. He also claimed that adenoids, when once pathologically enlarged, do not tend ever to atrophy, especially if during their existence any acute infectious disease has occurred.

In summarizing Dr. Logan called particular attention to the importance of: Early recognition and removal in children; care of naso-pharnyx in cases of acute infectious diseases; the fact that large faucial tonsils usually indicate the presence of adenoids, though the reverse is not true; in adults, that the condition is not rare, and when present, has persisted since childhood and not developed since puberty; and that operation is warranted and indicated in every case, to relieve present conditions and to prevent future complications.

HOW SHALL THE DIAGNOSIS OF POST-NASAL ADENOIDS BE MADE IN YOUNG CHILDREN, WHEN RHINOLOGICAL EXAMINATION IS IMPOSSIBLE?

DR. CLARENCE C. RICE of New York read a paper with the above title. He said that a rhinoscopic examination was usually impossible in children under seven years of age. He spoke of two classes of cases, one in which there is respiratory obstruction only occasionally and intermittently, with a small quantity of adenoid tissue; the second class where there is permanent obstruction and continuous mouth breathing, with a large quantity of adenoids. He said that a small quantity of adenoid tissue was present in 95% of cases, and that in these cases, where a mirror cannot be used, a post-nasal curette is useful for examination and diagnosis, and if the adenoids are found, — for immediate operation without anesthesia. He claimed that the curette was better than the finger, and that by its use in the above way and in the abovementioned class of cases, he avoided two attacks upon the frightened child, and made the diagnosis and did the operation at one time.

DR. FARLOW of Boston, in discussion of the foregoing two papers, said that he agreed with Dr. Logan that there were many cases of adenoids in the adult overlooked, that the condition was an important one, and should be operated upon in every case. As to Dr. Rice's use of the curette, he objected to it seriously as dangerous and painful. He spoke of and recom-

mended the inspection of the naso-pharynx in children through the nose, after the use of very weak cocaine or adrenalin, or both.

DR. MAYER of New York objected to the use of the curette as Dr. Rice recommended, and called attention to the presence of small lymph follicles on the posterior wall of the pharynx, looking like the so-called follicular pharyngitis in adults, in most cases of adenoids, as a valuable aid in diagnosis, claiming that they were almost pathognomonic of the condition.

DR. DELEVAN of New York, DR. MACKENZIE of Baltimore, DR. SWAIN of New Haven, DR. MYLES of New York, DR. SIMPSON of New York, DR. NEWCOMB of New York and DR. LOGAN of Kansas City all objected to the proposed use of the curette and to any operation without anesthesia.

DR. NEWCOMB also called attention to the occasional prominence of the atlas projecting into the naso-pharynx so far as to interfere with use of the curette.

SOME CASES OF FACIAL ERYSIPELAS FROM EROSIONS OF THE NASAL SEPTUM.

DR. JOHN W. FARLOW of Boston read the above paper, and spoke first of the frequency of cases of recurrent facial erysipelas, without apparent cause, that is, without evident wound on the face for the entrance of the infection. He noted the importance in these cases of a thorough examination of the nose, especially the septum, as that is the most common site of small nasal lesions. He detailed the histories of several cases of facial erysipelas, selected from a large number, in which an abrasion or erosion was found on the septum, and in which a thorough antiseptic cleansing treatment of the nose was the important part of the treatment of the case.

DR. BLISS of Philadelphia, in discussion, said that he thought it very remarkable that of all the many operations upon the nose, both inside and outside, so few cases developed erysipelas. He said he knew of only one case.

DR. KING of New Orleans and DR. JOHNSTON of Baltimore each reported a case of erysipelas following operation upon the nose.

DR. FARLOW in closing said that he presented these reports merely to call attention to the frequent small lesions of the nose as the probable point of entrance of the infection, and to urge the importance of a thorough routine examination and careful antiseptic local treatment of the nose in these cases of facial erysipelas.

SECOND DAY. — WEDNESDAY, MAY 13.

THE ARCH OF THE PALATE.

DR. SWAIN of New Haven read the above paper. He referred to the usual explanations of the high-arched palate, such as lack of functional use of the nose from obstruction, differences of atmospheric pressure, etc., and the extension of these causes as also determining deflections of the septum, and called attention to the fact that many children had a high-arched palate who had no nasal obstruction, and *vice versa*.

In the Flathead Indians, who deformed the heads of their children by depression of the vertex for the first year of their lives, the author found that the arch of the palate was very low (though the septum was not affected), showing that outside influences tending to alter the shape of the skull can and do affect the palate. He said that the deformities of the arch were due, not to any one cause, but to many and complex factors. The nose in these cases is usually a non-functionating organ. In the new-born babe the palate is above the level of the Eustachian tube, at puberty below it, — and consequently the palate has grown down away from the base of the skull, this being due to the downward growth of the superior maxilla, the septum and the pteregoid process of the sphenoid. From improper or no functional activity of the nose, this downward growth may be stopped; and perhaps because the nasal obstruction prevents the proper aëration of the maxillary sinuses, the lack of air causing non-development, or atrophy. The author also called attention to the added weight of the cheeks and inferior maxilla, dragging on the outer part of the superior maxilla, when the mouth was constantly open and relaxed, thus tending to pull the sides together and to narrow the arch. He said also that the shape of the adult palate, as well as the alignment of the permanent teeth, depends largely upon the preservation of the first teeth as long as possible. When noting the great results in adults of the comparatively slight force used by dentists in straightening teeth, and spreading them apart, the author thought it not unreasonable to grant that the forces mentioned above, when acting upon young, soft and pliant bones, might easily be sufficient to cause all the deformities found in these cases.

DR. DELEVAN of New York, in discussion, called particular attention to what, he thought, were the two most important points of the paper; namely, the care and preservation of the first teeth, and the early attention to any nasal obstruction.

DR. MAKUEN of Philadelphia referred especially to the importance of nasal breathing, and noted the estimate made by some observers, that 70% of all people breathe through the mouth at night, even when there is no obstruction to nasal breathing.

DR. KING of New Orleans said that while he had not made any actual measurements in the negroes of the South, he had observed that deformities of the palate and adenoids were not so frequent as in whites; that adenoids, when present, were not often associated with palatal deformities, and that as a rule the palate was larger and the post-nasal space more roomy, and that therefore adenoids when present did not cause so much obstruction.

ACQUIRED CICATRICIAL DEFORMITIES IN THE RESPIRATORY TRACT, DUE TO OTHER CAUSES THAN SYPHILIS AND TRAUMATISM.

DR. G. HUDSON MAKUEN of Philadelphia presented this paper, and in opening the subject said that cases of this kind were rare. He had sent a circular letter to three hundred laryngologists all over the country asking for information and data, and had received notes of 447 cases, in only 167 of which, however, was a definite cause assignable. Of these 16% were due to diphtheria; 8% to scarlatina; 3% to lupus; 1.6% to tuberculosis; 1.5% to a combination of scarlatina and diphtheria; 1.1% to typhoid fever; and .5% to measles. The author gave histories of two cases of his own, and argued that, in these common acute infectious diseases, more care and attention should be given to the treatment of the throat and nose.

DR. FARLOW of Boston said, in discussion, that while diphtheria might cause moderate adhesions, between the tonsils and the pillars of the fauces, or between posterior pillar and the posterior pharyngeal wall, he did not believe that it could cause any very extensive adhesions or contractions. He had never seen a case, and thought that in many cases the history was defective, and that the real cause was syphilis.

In connection with the papers on sinus disease DR. GEORGE B. WOOD of Philadelphia showed a number of sections of a head of a six months' old child, which were of special interest as showing the size and relations of the sinuses in a child of that age.

MY LATEST IMPROVEMENTS IN THE RADICAL TREATMENT OF CHRONIC SUPPURATIONS OF THE ACCESSORY CAVITIES OF THE NOSE.

DR. H. LUC of Paris presented this paper, and considered in order the maxillary, frontal, ethmoid and sphenoid sinuses.

I. *Maxillary sinus.* — The author stated first that radical surgical treatment was to be limited strictly to the chronic forms. He noted the distinction to be made between two classes of cases; first, the properly so-called sinusitis, with a primary infection of its mucous membrane; and, second, cases where the pus does not originate in the sinus, but merely accumulates there, coming from a frontal or a dental abscess. In the latter cases washing out the sinus may effect a cure, in connection, of course, with proper treatment of the source of pus, namely, the frontal or dental inflammation.

In the former cases puncture and washing should be tried first, and if unsuccessful, should be followed by radical operation.

II. *Frontal sinus.* — Dr. Luc referred to the Ogston-Luc operation, and spoke of the frequent poor results from it in cases of very large sinuses, due to the closing of the nasal drainage opening before the complete healing and obliteration of the cavity of the sinus. This unpleasant result had led many to go back to the old method of leaving the wound open, or to use the Kuhnt method of resection of whole of anterior wall, with its consequent great deformity.

Dr. Luc recommended and now uses the Killian operation, a combination of the Ogston-Luc with the Kuhnt and the Jansen operations, thus getting the immediate closure of the wound and nasal drainage of the Ogston-Luc, the opening of the floor of the sinus of Jansen's, and the removal of a part of the anterior wall of the Kuhnt method, but preserving a bridge of bone between the two openings which lessens the deformity, and extending an opening to the ascending part of the maxillary bone, giving opportunity to enlarge the fronto-nasal opening, and also giving access to the ethmoid cells.

Dr. Luc recommends this operation for cases with large sinus and the Ogston-Luc operation for cases of small sinus.

III. *Ethmoid cells.* — These the author said were practically never involved alone, but always in connection with frontal or maxillary inflammation. They may be attacked through the nose, or as a sequel to operation on frontal or maxillary sinus; but the author claimed that it was impossible completely to destroy the ethmoid labyrinth through the nose, as the anterior cells cannot be reached without making an external bony opening. He spoke of one case in which, operating intra-nasally, he opened accidentally into the sphenoid sinus. This did no harm and suggested a new route of operation on that sinus, which he had employed frequently since that time.

IV. *Sphenoid sinus.* — Here Dr. Luc said that we could operate by intra-nasal or by external method, always the former if the sphenoid sinus alone is affected, and if there is room in the nose to work; always the latter if the maxillary sinus is also affected, or if we cannot get room to work in the nose. He noted that it was important to remove a large part of the anterior wall of the sinus.

(To be concluded.)

Recent Literature.

Les Obsessions et la Psychasthénic. Par les DRS. F. RAYMOND et PIERRE JANET. Tome ii. 8vo. pp. xxiv, 543, with twenty-two illustrations. Paris: Félix Alcan. 1903.

The present volume is the only one of the work that has come to our hand, and therefore a satisfactory review is hardly possible. It contains reports of two hundred and thirty-six cases of various forms of obsessions, illustrating the detailed medical and psychological study of obsessions by Dr. Janet in the first volume of the work, but, without the introductory volume, the collection of cases, rich and varied as it is, loses most of its value.

THE BOSTON

Medical and Surgical Journal

THURSDAY, JULY 30, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

OBESITY IN YOUTH.

THE doctrines of diminished metabolism in obesity and excessive metabolism in youth have received decided opposition from the recent studies of Rubner,[1] who has investigated these questions under exceptionally favorable conditions. Two brothers, eleven and ten years of age, and approximately the same height, weighing fifty-four and eighty-nine pounds respectively, served as subjects for his experiments. Each of these boys spent four days in a respiration calorimeter, during which time detailed observations were made. As a result Rubner found that the normal boy ate proportionately more than his fat brother — fifty-two calories per kilogram body weight in contrast to forty-four calories. This apparent disparity, however, disappeared when the actual surface of both boys capable of radiating heat was taken into account. Making allowance for this, the diet was practically the same. The extent of body surface is quite as important in calorimetric observations as is the body weight, and disregard of this factor has been responsible for many erroneous conclusions concerning the food of fat people. An interesting, but only apparent, exception to this law is furnished by cachectic individuals and those rapidly emaciating. In such persons the number of calories required to maintain equilibrium is less than would be supposed. This is due to the actual skin surface and body surface in such individuals not being identical. The formation of folds of skin brings two surfaces into apposition, and the heat-giving area is thus diminished. Instead of diminished metabolic activity in obesity, Rubner finds the evidence more in favor of the opposite condition. He calculated that thirty-five per cent of the weight of the fat boy in the experimen was composed of fat tissue. The cells in the remaining two thirds of the body were compelled to do the work for the whole body, and thus each cell was forced to do more than its natural share. This doubtless explains the fatigue which fat people usually feel on even moderate exertion.

Variations in the natural amount of bodily activity between childhood and adult life, in the duration and depth of sleep and in growth are other influences too often neglected in the inferences which are drawn from experiments in metabolism. When these are considered, it is found that the same laws which apply to metabolic activity in adult life are applicable in youth. Rubner furnishes proof for this statement by comparing the diet of a dwarf with that of an infant of similar weight. The dwarf, who was twenty years of age, weighed fourteen and a half pounds (six and six-tenths kilograms), and ate eighty calories per kilogram. This closely approximated the diet of a baby, weighing eleven and one-tenth pounds (five and four-tenths kilograms), who ate seventy calories per kilogram. The slight difference in favor of the dwarf is explained by the work which he performed during the experiment.

The causes of the obesity in the case of the boy above mentioned were, of course, not accurately known, but they appeared to be due to lack of exercise from disposition and to peculiarities in the diet from necessity. As nearly as could be ascertained, albumen formed an unusually small per cent of the total diet. Further, it was found that the fat boy failed to absorb twenty per cent of the albuminous food which he did eat, thus reducing the total available albumen still more. The natural result followed that he ate a proportionately large quantity of carbohydrate food. Such a diet, low in proteids and rich in carbohydrates, is known to favor the laying on of fat, and the boy's natural aversion to exercise increased this tendency.

[1] Beiträge zur Ernährung im Knabenalter mit besonderer Berücksichtigung der Fettsucht. Berlin, Hirschwald, 1902.

NURSING AS A PROFESSION.

IN our issue of July 2d reference was made to the movement which is now well under way of providing further preliminary training for

those who intend to take up the work of nursing. With this movement, as we then implied, has naturally come a tendency on the part of the leaders in the work of nursing and others to claim for their calling a distinct place as a profession. We suggested that it seemed to us questionable whether nursing, as ordinarily understood, could be placed in the category of the liberal professions, but implied that in the nature of its work it was rather to be regarded simply as a "calling." This question must sooner or later be definitely answered. If nursing is to be regarded as a liberal profession, it must naturally claim the privileges which go with this designation, the most natural of which is to advance very far beyond the stage which it has as yet attained.

In this connection, we are glad to call attention to a letter on this subject which appeared in our issue of July 16, in which the writer took the position that nursing from its very nature could not be regarded as a liberal profession. He alluded to the fact that the essence of a profession is progress and that the work of nursing does not permit of such development. We are inclined to agree wholly with this view of the question. While perfectly willing to grant that it is altogether probable that a class of persons will arise from the ranks of nurses who will occupy some sort of a middle position between the physician and his patient, we nevertheless are strongly of the opinion that these persons will not be nurses and will not represent the plain drudgery of nursing as is at present the case.

A man of much acumen, himself a physician, once remarked to us that the future of medical practice would probably be that physicians would become consultants and that nurses would become essentially practising physicians. That we are still far from this state of affairs is apparent; nevertheless there are many things pointing in the direction of the progress of nurses beyond the limits of their chosen calling into those which have heretofore been regarded as the domain of the physician. We are not inclined to regard this by any means as an unmitigated evil. On the contrary, it seems probable to us that many of the procedures which the physician in the past regarded as his prerogative may be as well, if not better, done by a carefully trained person of wide experience, whether man or woman, but what we do claim is that this function goes quite beyond our conception of nursing, which, as we understand it, is simply and solely to take care of the physical and mental wants of the sick under the direct supervision of a physician.

The present state of affairs is certainly in a measure due to the attitude of the profession itself. It has been shown that women trained as nurses are capable of taking medical responsibility, and physicians have not been slow to lay such responsibilities upon them. The natural and inevitable result of this has been that nurses have looked beyond the details of their work, and have been allowed to believe that nursing requires a semi-medical education. We are not in the least attempting to criticise this point of view, but we are convinced that it is desirable to face the facts as they are, and possibly to speculate regarding the future to which the present tendencies are likely to lead. We are sufficiently optimistic to think that on the whole the elevation of women who still regard themselves as nurses will be of general utility; but we are strongly opposed to the idea that the term "nursing" may still be used to designate this class of persons, and that nursing, as now understood, may be regarded as a profession. This does not deny that it may grow into a profession which will then have a far closer analogy to medical practice than to our possibly somewhat old-fashioned idea of nursing as such.

JOURNAL OF THE ROYAL ARMY MEDICAL CORPS.

WE are in receipt of the first number of an English journal with the above title, edited by Major R. H. Firth of the Royal Army Medical Corps. It is stated that this journal is the realization of a hope of many years. The necessity for such a periodical has long been recognized by the medical officers of the army, but in spite of various efforts it has not been possible to publish the journal until now. The object of the publication is to print original articles by officers of the Royal Army Medical Corps and others, to present bibliographical notes on articles of importance to the military services, to reproduce work done by other military and medical journals and to provide information bearing upon the army medical services. The need of such a journal in England is strongly felt, and it is with the hope that liberal contributions will be offered that the journal has finally come into existence. The first number discusses the question of hospital arrangements on board transports, and contains other articles and matter of general medical interest.

In spite of the rapid increase in the number of medical journals, we are inclined to think that any periodical which tends to elevate and bring

into greater prominence the medical branch of the army is desirable and should find a distinct place of usefulness. Experience has shown that many questions concerning medico-military matters are ripe for discussion, and it is both natural and proper that officers of the medical corps should desire to have their own medium of publication. We have no doubt that this journal will be a success and add something of positive value to the well-filled ranks of medical journalism.

MEDICAL NOTES.

CONTAGIOUS DISEASES IN CHICAGO. — According to the *Bulletin* of the Chicago Health Department, only 57 cases of contagious diseases — diphtheria, measles, scarlet fever, smallpox, etc. — were reported during the week ending July 18. This is the lowest number since September, 1901. In the corresponding week last year there were more than twice as many, — 119, — and the 34 cases of diphtheria and 14 cases of scarlet fever reported this week are one third and one half less than the respective number reported during the previous week. Measles, which has been epidemically prevalent for many months, is fast disappearing, as also is smallpox, the solitary reported case of which was that of an unvaccinated infant of six months.

GIFT TO MCGILL UNIVERSITY.— It is reported that by the will of the late James Cooper sixty thousand dollars is left to McGill University as a fund to establish a chair in the medical faculty for the teaching and study of internal medicine. It is to be known as the Cooper Endowment Fund, and will be paid two years after the death of the testator.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, July 29, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 15, typhoid fever 18, measles 12, smallpox 0.

DR. SIMON FLEXNER A GUEST OF THE BOSTON FLOATING HOSPITAL. — On one of the trips of the Boston Floating Hospital last week Dr. Simon Flexner of Philadelphia was a guest. He is in charge of certain work of a bacteriological sort being done under the auspices of the Rockefeller foundation, and is making a tour of inspection of those laboratories where the experimental work is being carried on, one of which is the Floating Hospital.

BERI-BERI ON A NEW BEDFORD WHALER.— Beri-beri is a sufficiently unusual disease to make the following report of interest: A whaling vessel from New Bedford is said to have had while on her cruise an outbreak of this disease. Seven men are reported dead, and ten more of the crew ill. The vessel has temporarily put in to St. Helena.

APPLICATIONS FOR REGISTRATION IN MEDICINE. — The recently held examination of applicants for registration in medicine in Massachusetts is said to have demanded the largest committee room in the State House, owing to the fact that upwards of two hundred applicants applied for the examination. Five examinations for several years past have been given annually, but it is likely that this number will be increased with the increasing number of applicants.

NEW YORK.

CARE OF MOTHERLESS INFANTS. — The joint committee on the care of motherless infants has just presented its fifth annual report to the State Charities Aid Association and the New York Association for Improving the Condition of the Poor, the two bodies which it represents. The number of infants received during the year was 178, of which 62 have been adopted by families, 26 died and 90 remain in the care of the committee. Although many of the infants had previously been subjected to exposure, neglect or ill-treatment, the committee reports that during the last two years the death-rate among their charges has been actually lower than the general death-rate among children of the same age in New York City. An innovation made has been the employment of wet nurses, and most of these have been Italian women. "There are a physical vigor and warmth of nature in the Italian mother," the report states, "which make her a most desirable nurse. She learns to love the 'bambino,' for whom she cares with a strength she does not appreciate until the parting." A considerable number of the infants received are those taken to Bellevue Hospital from police stations.

NOTES FROM THE PHILIPPINES.

PREJUDICE AGAINST BOVINE VIRUS. — An incident showing the different phases which sanitation assumes in the Philippine Islands is the recent request which the Board of Health has made to the sanitary authorities in India for some "Amil" vaccine virus. There are a number of East Indians in Manila, and these object to being vaccinated with bovine virus, as the cow is to them a sacred animal, and to be inoculated with lymph from it would mean a loss of their caste. They do not, however, object to vaccination with humanized virus taken from some

member of the Amil caste, to which they nearly all belong, and the Board of Health is now endeavoring to secure some of this virus in order to vaccinate them in a way which will not arouse their prejudices and opposition.

SIMULTANEOUS CHOLERA AND BUBONIC PLAGUE. — Another interesting fact connected with the recent reappearance of cholera in Manila has been the simultaneous occurrence of cholera and bubonic plague in the same individual. This has happened in four instances during the past ten days, all the persons so affected being Filipinos. The double infection was diagnosticated during life in one instance, was shown to exist by the four autopsies, and the conditions were confirmed in each case by bacteriological examination. Such double infection, while unexpected, is readily explainable. The incubation period of plague may be nine or ten days, while that of cholera may often be only of a few hours' duration. Both plague and cholera are most liable to occur in those living under highly unsanitary surroundings, and who are most liable to contract anything in the nature of infectious disease which may be present, both as a result of their environment and habits. It is certainly quite possible that an individual with an incubating infection of plague, lasting a number of days before development, may acquire a cholera infection, having a comparatively brief period of development, during the incubation period of his plague infection, so that both may appear at about the same time.

DESTRUCTION OF LOCUSTS.— Another kind of opposition has been raised against the destruction of the locusts which swarm in countless myriads over the most fertile districts of the islands and do an almost incalculable damage to crops. The health authorities have been inoculating these swarms of locusts with the grasshopper fungus, which is proving an effective agent in their destruction. Locusts, dried, raw, baked, fried, stewed, ground into powder, etc., form a staple article of diet among the poorer class of Filipinos, who can collect them by the bushel with little labor. This class of natives is now violently opposed to the extermination of the locusts and loss of this food supply. The big land owners and "haciendors," however, are as strongly in favor of the destruction of these insect pests, and their wishes usually soon control public opinion among the surrounding natives. One who has never seen a swarm of locusts can form no idea of their vast numbers and the damage they do to crops. In the distance a flying swarm looks like a dense cloud of smoke or dust, and when such a swarm is passing overhead the sun is obscured. Settling on a field of rice or cane, they work so swiftly that the field soon looks as if swept by fire. The appearance of a swarm is the signal for every native to turn out with large scoop nets, bags and baskets, and vast quantities of insects are caught for food. A single sweep of a scoop net in a flock often yields half a peck of the locusts. The natives say that they are very sweet and palatable, and are particularly fond of them when fried to a crisp in cocoanut oil.

UNSANITARY CONDITION OF "ESTEROS." — There is some little popular complaint against the unsanitary condition of the "esteros," or sluggish creeks which are practically open sewers and ramify all through the city of Manila. As there is only about a two-foot rise and fall of tide in them, and at this season they lose the scouring effect of the daily rains, they have become very foul. Nearly all of them are shallow, and the falling tide exposes large areas of foul-smelling mud flats to fester under the tropical sun. A general scheme of drainage and sewerage for the city is being prepared, and no temporary expedient can place these "esteros" in a satisfactory condition. Many are choked up so badly that the tides do not flush them, and in the absence of heavy rains they become practically large cesspools. The mere cleaning of them would be extremely laborious and expensive, even if proper apparatus were at hand for performing the work. It is possible that by the removal of boats, logs and similar obstructions, and by the dredging out of a few bars, the sluggish currents may be quickened and the "esteros" made to cleanse themselves more satisfactorily. Whatever can be done, the Board of Health proposes to do, and if cholera does not again become severe in the city it will be able to give proper attention to such work. Of course nothing short of dredging, straightening their course, building up the sides of the esteros with masonry, filling in the low places and bogs, and flushing on the ebb tide from tidal reservoirs placed above the head of navigation will ever be satisfactory — a scheme requiring much time, labor and money for its execution.

MEDICAL INSPECTION OF IMMIGRANTS. — Hereafter all immigrants arriving in the Philippine Islands will be subjected to a medical inspection by the surgeons of the Marine Hospital Service. The medical examinations will be conducted in connection with the regular inspections by immigration officers; and such aliens as may be certified to by the surgeons to be insane, idiots or suffering from a contagious

or loathsome disease, or whose mental or physical condition is such as to apparently affect their ability to earn a living, are to be excluded from the islands. This additional task will be hard for the Marine Hospital surgeons, who are already greatly overworked, and entirely too few in numbers to meet the conditions in the islands.

Miscellany.

MUNICIPAL SANITARIUM FOR CONSUMPTIVES.

COMMISSIONER FOLKS of the Department of Public Charities, New York, has officially presented to the Board of Estimate and Apportionment the following recommendations regarding the establishment of a municipal sanitarium for consumptives: That the board request the Board of Health to select a site for such sanitarium at the earliest practicable moment, and, in co-operation with the Board of Trustees of Bellevue and allied hospitals, secure the necessary consents therefor; that the board request these trustees to co-operate with the Board of Health in these matters and to establish and maintain thereon, when the use of such site has been secured, a sanitarium for consumptives; that an appropriation of $30,000 be made, through the issue of special revenue bonds, to the trustees, to cover the cost of selection of site and maintenance during the remainder of the current year; that an issue of bonds to the amount of $400,000 be authorized for the construction by the trustees of a suitable sanitarium.

The commissioner's recommendations were accompanied with a report on the general subject to the mayor, as chairman of the board. In it is stated that a sanitarium which would accommodate 500 patients could be established for $407,000, and that the estimated expense of maintenance would be $1 a day for each patient. It is believed, however, that if sufficient land were provided to permit dairying, poultry-raising and fruit and vegetable growing, a considerable income might be had from these sources. The commissioner deems it important that the hospital should be located as near the city as possible, and he is convinced that a satisfactory site can be procured within fifty, and probably within forty, miles of New York. Thus conveniently located, it would be possible for the relatives and friends of the patients to visit them at a comparatively small expenditure of time and money; and this consideration, it is believed, would have an important influence upon the willingness of patients to go to the sanitarium. Having referred to a number of requirements for location, which after consultation with eminent medical authorities he regards as essential, the commissioner goes on to say that for a hospital to accomodate 500 patients there should be secured not less than 250 acres (preferably 400), and that land of the character desired should not cost more than $250 an acre. Regarding the type of buildings required, the report states that with the exception of administration and other service buildings, they need be only very inexpensive, as for dormitory purposes cheap wooden structures and tent cottages would probably be better suited to the needs of most of the patients than more substantial buildings.

The Board of Aldermen has already expressed its approval of the project, but should the Board of Estimate and Apportionment decide to adopt the recommendations mentioned, it is quite possible that there may be considerable difficulty in securing a suitable site for the hospital. After the passage of the act which authorized cities of the first class to select and purchase sites for sanitariums for consumptives, the committee on tuberculosis of the Charity Organization Society waited on the president of the Board of Health, and requested him to exercise the power and authority conferred by the law upon his department. Opportunity for action was promptly afforded; ninety-five acres of land being offered in Orange County, at a point said to be an admirable site for the hospital, the scheme of which had been carefully mapped out. The plan fell through, however, as opposition immediately developed from a sporting club which owned territory adjacent to the proffered tract. The influence brought to bear upon the legislature was strong enough to secure the working through of a bill which, as has been mentioned in the JOURNAL, added to the restrictions on the establishment of such hospitals the consent of the county and local supervisors. In the city Tuberculosis Infirmary on Blackwell's Island, there were on July 1 three hundred and ninety-one patients.

Correspondence.

ALCOHOL *VERSUS* ALCOHOLICS.

BOSTON, July 26, 1903.

MR. EDITOR: Among several valuable points in the paper upon alcohol by Dr. R. C. Cabot, printed in last week's JOURNAL, one not least in value is the recognition that experiments upon well men are not exact indications of the action of alcohol upon the sick. Another is criticism of the attempts to judge of the effect of therapeutic doses by means of observations upon toxic doses.

Permit me to suggest yet another fallacy running through much of the current discussion upon this subject, one which Dr. Cabot suggests, but upon which he lays much less stress than upon the two already mentioned, — I mean neglect to consider the combinations in which alcohol is given. When a laboratory man says alcohol, he means alcohol. Clinicians, however, have formed an unfortunate habit of speaking of wines, spirits, etc., as alcohol, ignoring the presence of sugar, water, acids, ethers, hops, peat, smoke and so on. To assume without inquiry that these articles have no effect is unscientific. In some cases it is to assume that which is at least improbable. Whether true or not, it is a matter of common report that drunkenness differs somewhat according to the drink that has produced it. Again, there are patients who can drink brandy but not whiskey; others who can drink American whiskey but not Scotch; the penalty in each case being a disturbed digestion. It is at least possible that temperature, blood pressure and the rest may also be affected by the other ingredients of wines, for instance, as well as by the alcohol which they contain. Thus, for clinical purposes, the valuable work begun on alcohol must be supplemented by similar work on alcoholics. Above all, we must not confound the one with the other.

Yours truly,

EDWARD M. BUCKINGHAM.

RECORD OF MORTALITY

Deaths reported, 3,800; under five years of age, 1,577; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,371, acute lung diseases 266, consumption 331, scarlet fever 31, whooping cough 19, cerebrospinal meningitis 4, smallpox 22, erysipelas 3, measles 25, typhoid fever 54, diarrheal diseases 702, diphtheria and croup 78.

From whooping cough, New York 2, Chicago 5, Philadelphia 5, Baltimore 1, Pittsburg, Boston and Lowell, 1 each. From erysipelas, Philadelphia, Boston and Worcester, 1 each. From smallpox, Philadelphia 14, Pittsburg 8.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending July 4, the death-rate was 14.4. Deaths reported, 4,169; acute diseases of the respiratory organs (London) 164, whooping cough 109, diphtheria 53, measles 106, smallpox 7, scarlet fever 37.

The death-rate ranged from 5.3 in Hornsey to 23.3 in Merthyr Tydfil; London 13.9, West Ham 13.1, Brighton 11.2, Portsmouth 15.5, Southampton 12.3, Plymouth 17.2, Bristol 13.5, Birmingham 13.9, Leicester 11.6, Nottingham 16.5, Bolton 15.6, Manchester 17.1, Salford 13.8, Bradford 14.0, Leeds 14.2, Hull 14.8, Newcastle-on-Tyne 16.7, Cardiff 16.3, Rhondda 12.2, Liverpool 19.0, Coventry 17.9.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, WEEK ENDING JULY 25, 1903.

J. C. BOYD, medical director. Commissioned medical director, with rank of captain, from June 20, 1903.

E. O. HUNTINGTON, surgeon. Detached from the "Maine" and ordered to the Naval Hospital, Navy Yard, New York, N. Y., for treatment.

R. K. SMITH, A. W. DUNBAR, A. FARENHOLT, C. P. BAGG, E. J. GROW, M. S. ELLIOTT, surgeons. Commissioned surgeons with the rank of lieutenant-commander, from March 3, 1903.

R. W. PLUMMER, passed assistant surgeon. Ordered to the "Maine."

C. E. RYDER, J. A. RANDALL, assistant surgeons. Appointed assistant surgeons with rank of lieutenant, junior grade, from June 26, 1903.

C. P. KINDLEBERGER, surgeon. Ordered to the "Independence."

A. STUART, assistant surgeon. Granted sick leave for two months.

G. P. LUMSDEN, surgeon. Detached from the Naval Station, Port Royal, S. C., August 1, and ordered to the Torpedo Station, Newport, R. I.

R. M. KENNEDY, surgeon. Detached from the Torpedo Station, Newport, R. I., and ordered to the "Dixie."

A. H. WISE, C. T. GRAYSON, acting assistant surgeons. Appointed acting assistant surgeons, with rank of lieutenant, junior grade, from July 14, 1903.

P. L. COCKE, acting assistant surgeon. Detached from the "Chesapeake" and ordered to the Naval Hospital, New York, N. Y., for treatment.

BOOKS AND PAMPHLETS RECEIVED.

The Practical Medicine Series of Year Books, comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued Monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. VII. Chicago, Ill.: The Year Book Publishers. June, 1903.

International Clinics, a Quarterly of Illustrated Clinical Lectures and especially prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene and other Topics of interest to Students and Practitioners. By Leading Members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., with the collaboration of eleven other physicians, with regular correspondents in Montreal, London, Paris, Berlin, Vienna, Leipsic, Brussels and Carlsbad. Vol. II. Thirteenth Series. Illustrated. Philadelphia: J. B. Lippincott Co. 1903.

A Text-book of Surgery for Students and Practitioners. By George Emerson Brewer, A.M., M.D. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1903.

The Medical Epitome Series. Microscopy and Bacteriology. A Manual for Students and Practitioners. By P. E. Archinard, A.M., M.D. Series edited by V. C. Pedersen, A.M., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

Address.

THE SHATTUCK LECTURE.

THE SOURCES, FAVORING CONDITIONS AND PROPHYLAXIS OF MALARIA IN TEMPERATE CLIMATES, WITH SPECIAL REFERENCE TO MASSACHUSETTS.*

BY THEOBALD SMITH, M.D., BOSTON.

(Concluded from No. 5, page 118.)

On the West Frisian coast, similar work was carried on by natives from 1888 to 1900 without the appearance of malaria. In 1899 to 1901 the work was done by Dutch laborers of the company furnishing the party above referred to and malaria appeared. These laborers came from a region in which malaria is endemic. Near the mouth of the Ems River malaria appeared during the construction of harbors and a lock on which one hundred Italian workmen were engaged. This subject is considered of so much importance that the government has established a special laboratory at Wilhelmshafen, where construction work is being carried on to prevent the outbreak of malaria among the workmen and the inhabitants. Anopheles is abundant in the localities referred to.

Among the outbreaks of malaria which are of more than usual interest are such as occur among the inmates of schools, prisons and institutions of one kind and another. Persons are now and then attacked who have been confined as prisoners.

The few instances which have come under my immediate observation were always near breeding places of Anopheles, and some of the inmates, gathered together from various localities, were evidently old cases of malarial infection or else from places where malaria is endemic. In several cases such persons would reveal their chronic infection by passing through an attack after they had left their home in the endemic territory and settled down in their new abode.

Martini [54] has recently given a very plausible explanation of the early and repeated occurrence of malaria in certain houses. The curves of malaria in the endemic region of North Germany show two maxima: one in April – May, the other in August – September. Last year Martini came to the conclusion, after a study of the local conditions, that the early cases are due to hibernating mosquitoes which are called from their hiding places by the great warmth of the dwellings. They feed upon the blood of persons who have passed through attacks the previous season and find sufficient warmth in the houses to mature and transmit the parasites to other persons in the same dwelling.

There are certain warm days in March and April when mosquitoes leave their hiding places and sting vigorously whenever the opportunity offers. This year March 14 was one of these enticing days, and I was able to capture a considerable number of females. In a school not far from Boston, situated in a locality favorable to *A. maculipennis*, the first case appeared on April 8. The infection was probably carried by mosquitoes which swarmed March 14, and which infected themselves on that day or later from some latent case dating back to a former season. We should expect to encounter cases about three weeks after such early warm days, which allows for the ripening of the sporozoites and the period of incubation of the new case.

It might be supposed that malaria, once established in a house, can pass from one member of a family to another and that cases may be looked for every three weeks during the mosquito season. If this were true, the contagious character would have been recognized long ago. In the foregoing pages I have endeavored to show why this would not be likely to occur. The patients attacked are treated promptly and gametes cannot form. It may also occur that unusually susceptible persons, even if not treated, do not form gametes for a time. Occasionally, however, the successive illness of members of the same family is noticed. Thus, Dr. Bronson, in the report from which I have already quoted, made the following statement in 1871:

> The frequency with which the several members of a family, in a previously healthy neighborhood, have sickened one after another when once the complaint was introduced, often suggested to Dr. Barker the old idea of contagion. It must be admitted that authority is opposed to this idea, but I do not think the question yet settled.

In looking over some records which I collected with considerable care about six years ago, in a town then recently infected with malaria as a result of extensive public improvements, I find that house epidemics did not figure to any extent. In one family, consisting of two adults and five children, the father was taken with quotidian chills, and a child three years old who slept with him was attacked with tertian fever three weeks later. Here there is some evidence of transmission, but it may have been an accidental coincidence.

In a family of six the father was attacked in May, but no other members subsequently. In a family of nine, consisting of the parents and seven children, the father and a child two and one-half years old were attacked in July, within a few days of each other. No other cases occurred later.

In a family of four, only the mother was attacked, in July. In a family of five, only the father was attacked, in August. In a family of eleven, mostly grown up, two daughters were attacked within a few days of each other, in August. About a month later one other member was taken ill.

A number of other illustrations might be given which would bring out substantially the same fact: large families of whom but one or two, rarely three, are attacked, and usually simul-

*Delivered before The Massachusetts Medical Society, June 9, 1903.

taneously. The houses do not become foci of the disease.

The facts which have been cited to show that houses do not necessarily retain malarial infection, probably because the blood of the diseased members does not produce fully ripe gametes, naturally leads to that very important phase of our subject which relates to the spontaneous disappearance of malaria.

A fact which stands out prominently in the eminently interesting chronicle of New England's ague spots is the disappearance of this malady after it had prevailed for a time. Tradition represents it very prevalent in the earliest colonial days, but the practitioners of the early quarter of the nineteenth century did not see much of it.

The testimony from various parts of the temperate zone seems to be the same, that places once malarial are now entirely free. Certain portions of England, France, North Germany, and the Netherlands have passed through periods of malarial endemicity. In such places Anopheles are still present, but the virus has disappeared. Farther south the process may have been the reverse of this. The territory about the mouth of the Tiber, now thoroughly infected, used to be a summer resort for the Romans. The Roman Campagna shows signs of former active cultivation and occupation. In our own state, the epidemics associated with public works have, as a rule, promptly subsided after the work was completed, and in some instances almost completely disappeared.

This transient visitation of intermittent fever may be ascribed, in our climate at least, to several causes, chief among which is the prompt treatment of the disease and the consequent incapacity of the patient to infect mosquitoes. The general conditions are also quite unfavorable. Among these are the thin population in the rural districts, the scattered homes, the general scarcity of mosquitoes of the genus Anopheles, the occasional cold summers and the seasonable interruption of the propagation of mosquitoes by winter. Where one or more of these conditions unfavorable to transmission are suppressed, as in years of drought, in a dense rural population near stagnant water, or among an illiterate, ignorant class of people among whom cases go untreated, endemicity may reasonably be expected. The longer it is allowed to proceed unchecked, the more difficult its final eradication.

The disappearance of malarial infection from large territories in European countries is probably due to the decrease of wars of invasion, and hence of camp life of soldiers in infected regions, and of infected soldiers from malarial regions in territory hitherto free from infection. The lack of any systematic use of quinine greatly aided the disease under these conditions.

The spontaneous disappearance of malaria is an indication that it was forcibly and overwhelmingly imported at one time, and that it cannot re-establish itself except under certain new industrial conditions, simulating camp life in many respects, such as the laborers' camps, rural schools, prisons, hospitals and factories.

In the foregoing brief review of the incidence of malaria in our state, I have purposely avoided going into detail concerning local epidemics which I have examined more or less in detail. The reader may readily consult for himself the published documents referred to at the end of this paper, in which the essential data have been brought together.

Though much has been written upon this subject, the student finds great difficulty in utilizing past evidence because there is, as a rule, complete silence concerning the, to us, most important factor, the human carriers of the infection. It is for this reason that I have been induced to step slightly beyond the bounds of the severely critical treatment of evidence in this lecture. My object has been to stimulate physicians throughout our state to collect facts from the new standpoint, for only in this way can the views maintained in this paper be rigorously tested. All biological research of medical problems must finally meet its fate for good or ill by being confronted with the human patient, and this confrontation rests entirely in the hands of the physician.

PROPHYLAXIS.

It would be unfortunate if, after the tendency of our city population to spread into the country had been fully established, malaria should come to fasten itself upon such population and drive it back into the heart of the cities. There is at present no immediate prospect of such a calamity, yet the increase of rural population in density without adequate improvement in environment might lead gradually to endemicity of malaria.

The number of people in our state, living in an essentially rural environment is larger than is generally supposed. The twelfth census gives the total population of the State as 2,805,346. In eleven cities, having each a population of over 40,000, the total number of inhabitants is approximately 1,228,000. Of this number, many live in the outskirts in what is practically rural environment. This class may be allowed to offset those living in the heart of the smaller cities, not included in our estimate, leaving about one and one-half million inhabitants as country residents. Of the other half, the larger number visit the country more or less and are, to a certain degree, exposed to prevailing malarial influences.

The means to be resorted to, in preventing and suppressing malaria, will, without doubt, occur to those who have read the foregoing pages, and any special suggestions may seem superfluous. Yet, in view of the danger which is always likely to beset the awakening public sense and responsibility of going from one extreme to the other, from ignorance and apathy to a too vigorous, wasteful and often injurious campaign, it seems best briefly to summarize the conditions to be

met and the simplest means of attaining the desired end. The two things plainly to be done are to suppress Anopheles as far as possible and to shield the malaria patient so that Anopheles cannot become infected.

In localities where malaria is not known to exist, but where there are breeding places of Anopheles, the destruction of such breeding grounds is not essential from a public health standpoint. If, however, in such or similar localities, public works are to be undertaken, the situation is entirely changed. Great care must be taken to prevent the introduction of malaria. There should be, at the outset and before any digging or other open-air work is undertaken, a thorough biological survey by a competent person of the entire locality which may come under the aerial influence of such work. Breeding places of mosquitoes should be carefully noted and plotted on a suitable map. For this purpose the inspection should be made in the spring, the summer and the fall, as the conditions are likely to be quite different in different seasons. Allowance should be made for drought and the conversion into breeding places of bodies of water free from mosquito larvæ during seasons of ordinary rainfall.

The effect of the work to be undertaken upon drainage, either temporarily or permanently, should be carefully considered. Especially the building of embankments and roadways should be allowed only when their probable effect upon surface water is not favorable to stagnation. Excavations for brickyards, for material for roadways, trolleys, etc., should be forbidden if the ground water level will be exposed thereby and a stagnant pool created. The sins of railroad building, committed in the past, are numerous and practically irremediable. No new ones should be permitted. One of the richest breeding grounds of Anopheles about Boston with which I am acquainted is a triangular piece of marsh completely shut in by railroad embankments and converted into a fresh water pool.[55]

The treatment of existing breeding places, before and during the progress of work by gangs of laborers, may be palliative or radical. The palliative method, now so well known, consists in covering the surface of stagnant, mosquito-breeding bodies of water with some grade of petroleum oil. The oil, which is scattered over the surface by pouring, by spreading with a broom dipped into the oil, or by the use of pump and hose with sprinkler, etc., forms a thin film which interferes with the respiration of the larvæ and kills them. The film disappears by evaporation and must be renewed every two or three weeks, according to conditions.* The amount of light fuel oil required is approximately one ounce to fifteen square feet, according to Howard. According to Kerschbaumer (60, p. 119) one square meter requires somewhat more than 0.5 liter of petroleum to completely cover the surface. This would be approximately 21 oz. to 15 square feet. Why he uses so much I am unable to explain. Palliatives in the shape of petroleum or its combinations should not be used upon water unless the larvæ of mosquitoes have actually been found in it. The interference with the normal aquatic life may lead to as yet unrecognized, undesirable results.

A vigorous campaign against all mosquitoes was waged during 1901 and 1902, in the town of Brookline under the local board of health, by Dr. H. L. Chase, and described by him recently.[57] This work done in our midst, and adapted to conditions prevailing in our state, may well serve as a model and guide for other towns where a destruction of all mosquitoes is desired.

Wherever the breeding can be suppressed by natural methods as contrasted with the artificial one of poisoning or asphyxiating the larvæ it should be done. In level meadows the open ditches, if more or less continuously filled with water, should be replaced by some form of covered drains. Shallow pools in which fishes cannot subsist should be filled up. Brooks should be kept free from débris washed down or thrown into them. Such débris provides quiet pools where larvæ are usually found if not elsewhere. The larger streams and rivers usually are free, but the banks should be searched for detached pools. In case of very small rivulets, ditches or brooks, some flushing device may be useful. The water may be dammed for a certain length of time and then discharged all at once. The larvæ will be swept into larger bodies of water and there destroyed.*

It is of interest to observe the want of topographical knowledge of suspicious bodies of water on the part of intelligent inhabitants. We may truly speak of the unexplored wilderness of the average town brook. The land is cultivated to within a certain number of yards of such a brook or stream and an impenetrable tangle of vegetation guards it from intrusion on both sides. Its presence even may be unknown to many who have frequently glanced at the line of bushes and stunted trees under which it is concealed. It has been claimed that mosquitoes will not breed in water thoroughly shaded by trees, shrubs and other vegetation. This may be true to a certain extent, but larvæ are certainly found in shaded pools. In any event, our brooks should be made accessible to inspection even though the vegetation on the banks be largely preserved. Even the greatest care in maintaining the bed of a brook free from obstructions may not avail in times of drought. Pools will form and larvæ will appear in them. Occasional petrolizing or flushing may then be necessary if malaria prevails.

Swamps are usually regarded as fertile sources of mosquitoes, and if actual inspection should prove that the suspicion is true, petrolizing, per-

* Recently a proprietary substance known as Phinotas oil has come into use. It is said to represent some combinatoin of petroleum. It sinks to the bottom when applied and subsequently rises again. It is said to kill all life in waters treated with it.

* I found after writing this that Kerschbaumer has also recommended this device of periodic flushing, especially in dry seasons (60, p. 130.)

manent flooding, or drainage are the only remedies. Not all swampy ground favors mosquitoes, however. I have repeatedly been surprised in failing to find a single specimen in them.

The expansion of our systems of parks and reservations, and the increasing patronage which these open-air spaces are receiving from the public housed in the heart of our cities, make it more and more necesssary to inspect for mosquito larvæ the bodies of water, usually artificial, which are scattered over these reservations. Neglect of this precaution might easily convert our parks into centers for distributing malaria to a population otherwise sheltered from it in the confines of the city. Squads of laborers are frequently employed in the reservations and may infect the mosquitoes. I recall one case in a child living near a large park whose infection could hardly have come from any other source.

Since excavation and other out-of-door work may be undertaken at almost any time in the suburbs of cities, the campaign against the mosquito in such territory should not be allowed to flag, but should be pushed vigorously until all breeding places have been destroyed or at least controlled by sanitary authorities.

The frequent appearance of malaria in the heart of cities at present is in many instances traceable to extensive excavations near by, but considering the summer exodus from our large cities, which includes almost every one nowadays, if only for a half holiday, the sources of urban malaria may be many, and impossible to locate.

In rural communities rain-barrels and open catch basins, which are usually inhabited by Culex larvæ, should also be searched to note any Anopheles larvæ which may have acclimated themselves. Privy vaults have been found to be good breeding places for Culex in regions farther south.

Fortunately for us, salt marshes, though very prolific in mosquitoes of the genus Culex, do not form breeding places for Anopheles. The immunity from malaria of our seacoast and the banks of estuaries under tidal influence has long been known, and it forms an agreeable confirmation of scientific studies which eliminate Culex as transmitters of malaria.[55] The late Dr. Greenleaf,[58] who had given much attention to intermittent fever about Boston, showed that the estuary of the Charles River as far as Watertown could not be regarded as a factor in malaria, as there were no cases along the river bank. He also found the park police along the estuary free from malaria.

The extermination of the hosts of mosquitoes bred in such marshes does not come within the scope of this paper. It may, however be said that if attempts made to drain such marshes of the salt water are successful, care must be taken to exclude fresh water from low places in them, otherwise Anopheles may move in where Culex was driven out.

During the progress of open-air work requiring the employment of large bodies of men who must live in camps, there should be in addition to a thorough control of the breeding places of mosquitoes an equally thorough sanitary supervision of the laborers.

Since much of the infection of mosquitoes and human beings goes on after dark, the camps should not be placed near the center of population nor near small bodies of water, unless the latter can be kept free from larvæ. The laborers should be inspected from time to time, and any suffering from malaria removed to some hospital or other place where they can be adequately protected from mosquitoes. Notification of the disease among the inhabitants should be insisted on at such times, and the sale of quinine by druggists reported to the local health authorities. Where the Anopheles mosquitoes cannot be satisfactorily controlled, the laborers' camps should be well screened and the latter forbidden to move about after dark. Whenever the mosquitoes are properly taken care of, the personal freedom of the laborers need not be interfered with to this extent.

It would be of interest to study carefully the health of any town where large public works are being carried on with foreign labor but where the workmen scatter after dark to different houses; also where native labor is being employed exclusively.

Where malaria has been prevalent for some years, and where it has assumed an endemic character by cropping out under various conditions in the inhabitants, as a result of latent infection, the difficulty of completely eradicating the infection is great, because the number of carriers of the parasite is large and mosquitoes may infect themselves readily. Under such circumstances, it will generally be found that the watercourses, swamps and ponds have been sadly neglected by an indifferent, indolent public. Streams are used as depositories for all kinds of refuse and the conduits are out of repair. Sometimes railroads are to blame for cutting off portions of ponds, lakes, etc., and converting them into stagnant swamps. In some places, improvements undertaken years ago have left the territory more favorable for mosquitoes. In one town I saw an abandoned portion of a river bed favorable for breeding mosquitoes which had been left by the artificial straightening of the course of the river. In almost any town signs of some past favor to mosquitoes, ignorantly bestowed, are found by the interested observer.

Vigorous effort to reduce the mosquitoes coupled with popular instruction concerning personal protection against mosquitoes, prompt treatment of individual cases and the necessity for concerted action, should succeed in every case in a climate like our own. Such success may not be realized for several years, because the people can only gradually rid themselves of latent infection.

In all efforts to suppress malaria by the destruc-

tion of mosquitoes it should be borne in mind that those breeding places nearest the bulk of the population should be attacked first and then, with increased means and assurance of success, the territory under surveillance should be gradually expanded. Breeding places over half a mile from dwellings are regarded by many observers as not likely to be of much consequence, yet they should be dealt with, if possible, for they serve as a source for the stocking of nearer territory.

The question naturally arises in our minds in reflecting upon this important subject whether, with increasing density of population, malaria will eventually succeed in fastening itself permanently upon the state in spite of efforts made to prevent and suppress it along the lines indicated. Fortunately no capital spent upon the radical extermination of the mosquito will be wasted. Whatever is done in this direction will redound to the general good of the people. The campaign against the mosquito will lead to a general cleaning up and to the cultivation of waste land; it will acquaint us with our own brooks now overgrown and concealed; it will tend to bring our dispersed and shattered streams back into their natural beds by the removal of unnecessary dams; it will prevent the private transportation interests from riding roughshod over the land, gouging out here and there unsightly holes and leaving them to choke up with water plants. Intensive cultivation will do much to repair the damage done by neglect of arable land. We shall be even more careful about permitting the pollution of our streams than heretofore if, as I believe, it tends to favor the mosquito larvæ.

The success of the struggle against an endemicity of malaria is favored by our climate, which is purified annually by frost. Only a comparatively small number of mosquitoes survive, and these must re-infect themselves again in the spring. Even under very favorable conditions it takes a whole summer for them to gather enough momentum to produce an epidemic in the late summer and early fall, when the frost again sweeps them away.

On the other hand, there are increasing difficulties to contend with, as the growth of population continues. The cosmopolitan character of our immigration and the steady stream of people from malarial foci in Europe tend to keep up the supply of infection in our midst. The tendency of gathering a fairly dense population in mill-towns, often in the midst of extensive breeding grounds of mosquitoes, makes them compare well in opportunities for infection with the migrating and transitory laborers' camp. Fortunately this *urbs in rure* population at present does not come from malarial districts to any extent, and hence they have been comparatively free from malaria with a few marked exceptions.

We must also bear in mind that we have arrayed nature herself against us in this struggle against a malarial climate. The great fluctuation in the volume of water in our streams from season to season, the resulting tendency toward bringing down large quantities of silt during freshets, which gradually choke the currents in the low lands and cause the stream to widen as it grows shallower, are all processes in favor of the mosquito. The deforestation of the land feeding these streams is largely to blame for these conditions, and, as it continues, who may feel certain that our descendants living in the rich river valleys may not assume the sallow hue of malarial cachexia and drag along a miserable existence for which the greed of their forefathers is mainly to blame? It is safe to predict that there will not be enough physical vigor in these descendants of a highly conventionalized nation to successfully imitate the immunizing capacity of the African native. They will give way to more sturdy immigrants or else the land will be abandoned.

In sketching this future possibility, I do not wish to be discouraging, but simply to stimulate our people because we have still in our grasp the chances for ultimate success.

It is to be hoped that as our control over malaria increases, the paralyzing sensitiveness of communities upon this matter may give way to a more active co-operation with the investigator who is endeavoring to elucidate the local causes of the disease and who is powerless, without the assistance of the public and the medical profession, to make an adequate investigation. The hearty co-operation of the members of the medical profession is of special importance, since they meet the disease in its only visible manifestation, the paroxysm in the human subject. In nearly every community some one or more physicians may be found who are prepared to assist and give their time, who are personally interested in the scientific problems involved and their practical value, and who are prepared to meet the slow returns of science by adequate outlay of time and strength. To many of these I am indebted for valuable assistance given ungrudgingly. With the continued co-operation and assistance of these disinterested helpers, medical science may be able to solve the many minor problems which still surround this subject, and public health may be in position soon to deal more firmly and radically with local causes.

SUMMARY.

(1) There is no evidence that any but the tertian form of malarial fever can be propagated in Massachusetts.

(2) The original source of tertian infection must be looked for in the blood of individuals coming from permanently infected localities in our own country and in Southern Europe.

(3) There is no definite information as to the stage of disease or relative immunity in which mosquitoes may become infected, but analogy with similar diseases of animal life indicate that the gametes are not formed early in the disease, and that relatively immune persons are the most dangerous, especially after fresh exposure, be-

cause in them gametes form very promptly without causing much or any clinical disturbance.

(4) The dissemination of infection is most easily promoted in our latitude when people live in a crowded condition, unprotected from mosquitoes and near breeding places of Anopheles.

(5) The decline and disappearance of malaria after importation and epidemic prevalence is in part due to relative isolation of the inhabitants and protection by quinine and from mosquitoes, and in part to the absence of persons partially immunized by long exposure in endemic localities.

(6) There is some evidence that sewage pollution in surface waters favors mosquito larvæ directly, through increase in food supply; indirectly, by injuring their enemies.

(7) Since malaria may be latent and hence unrecognized, and since it is largely a disease of the lower classes whose movements it is difficult to control, the best method of reaching it is to suppress the mosquitoes whenever possible.

(8) Malaria is of sufficient importance to become a notifiable disease.

(9) Infants and children exposed should have their blood examined during any disturbance of health.

(10) In times of epidemic malaria it may become necessary to make special regulations governing infected persons.

(11) It is of great importance that the relation of the widely distributed species, *A. punctipennis*, to the parasite of tertian fever be accurately determined.

(12) It is also highly desirable to test the infecting power of fresh cases of tertian fever as compared with relapses and with individuals from malarial countries.

THE ELEMENT OF TORSION IN LATERAL CURVATURE OF THE SPINE: ITS PLACE IN THE CAUSE AND TREATMENT.[1]

(Third Paper.)

BY ROBERT W. LOVETT, M.D., BOSTON.

IN spite of the present activity in orthopedic literature on the subject of rotary lateral curvature of the spine, our present knowledge of the mechanics of the affection is very inexact, and treatment for this reason is necessarily largely empirical. The explanations of the phenomena of scoliosis and the study of its mechanism have been written from a study of the especial structure of the human spine, particularly the distorted scoliotic spine. The curves of the articular processes have been studied, the shape of the individual vertebræ has been analyzed, the physiological curves have been considered, and a large amount of work has been expended [2] upon this side of the question. This literature occupies a large space, but has proved of little practical value.

The present paper is an attempt to study the element of torsion in its relation to lateral curvature, a study not of the anatomy but of the movements of the spine.

The anatomical work was done at the Harvard Medical School, and the writer is indebted to Prof. Thomas Dwight of the Harvard Medical School for his anatomical material and for the benefit of his criticism, to Prof. I. N. Hollis of Harvard College for help on the mechanics of the problem and to Dr. H. O. Feiss of Cleveland for much help in the experimental part of the work.

If one considers the human spine from the point of view of its evolution, one finds that the spinal column in its simplest form (Cyclostomata) consists of a homogeneous non-segmented flexible rod. The articular processes first appear in some of the fishes (Rays and Teleostei), and are general in the Amphibia (Gegenbauer).

The spinal column in the lower fishes is a simple flexible rod consisting of a series of disc-like vertebræ bound together by intervertebræ elastic discs without articular processes. Higher in the vertebrate group one finds elaboration of structure and the formation of permanent anteroposterior ("physiological") curves, along with modifications of the shape of the vertebræ. But articular processes seem to have developed in the line of incidents rather than essentials, and in the higher forms have carried out rather than radically modified the behavior of the simple fish's backbone, which is in mechanical terms a straight, flexible rod.

Articular processes in the human spine from the point of view of their evolution are therefore to be regarded as the resultants of use rather than as factors determining of themselves the motions of the spine. They are the result rather than the cause of the behavior of the spine.

The questions at issue are these:

(1) Why does rotation of the spine on its vertical axis occur in lateral curvature?

(2) If lateral curvature is necessarily associated with rotation or torsion, may not the reverse be true, and may not rotation of the spine be necessarily accompanied by lateral curvature?

On theoretical grounds Meyer came to the conclusion, in 1865,[3] that the articular processes were not the cause of torsion, but that torsion was due to the fact that the human spine was composed of two elements, the column of bodies and the column of arches; and that as the two columns

[1] Read before the American Orthopedic Association at Washington, May 14, 1903.

[2] Riedinger. Morphologie und Mechanismus der Skoliose, Wiesbaden, 1901.

[3] Meyer: Virch. Archiv, 1865, Bd. 35.

possessed a different degree of elasticity, side bending must result in a torsion, since these two elements of the column did not respond in the same degree to side bendings. Since Meyer's view after long years of neglect has again come to the front,[4] it becomes of importance to examine the following aspects of the question:

(*a*) Do the articular processes determine or cause torsion of the spine?

(*b*) Is torsion caused by the fact that the spine consists of two elements of different elasticity?

(*c*) Does the spine as a whole behave as would a flexible rod of the same size and shape independently of the two factors mentioned above, and may not torsion be explained by this fact alone?

In order to determine whether the articular processes cause torsion, and whether the united action of the two components of the human spine, the bodies and the arches, is necessary to produce torsion of the human spine in side bending, the following experiment was made:

The column of vertebral bodies was removed from an adult cadaver by cutting the pedicles of each vertebra, and the column of vertebral bodies was observed by itself. In all respects it behaved as does the intact spine with ribs attached. Rotations and twistings followed the same formulæ as in the flexible rod and also the same formulæ as in the intact human spine. Even the lack of torsion movement in the lumbar spine, supposed to be due to the close interlocking of the articular processes, existed in the column of bodies, entirely independent of articular processes.

This demonstrated that neither the articular processes nor the different elasticity of the bodies and arches was necessary for the production of torsion in side bending, but that such torsion occurred in the column of vertebral bodies alone, and that the column of vertebral bodies alone did not differ in its behavior from that of the intact human spine.

Since then the whole spine behaves as would the column of bodies alone, and since the history of the spine in its evolution is that of a flexible rod increasing in complexity of structure, an investigation was then commenced to see if the spine in its movements did not behave as would any flexible rod of similar size, shape and elasticity. If such is the case, it would obey the laws of physics governing flexible rods, and as a passive instrument under certain conditions it must assume certain positions and could not assume others so long as its structure was intact, just as a carriage will go backward or forward or may be turned to the right or left but will not go up or down or sideways. It does not matter whether the carriage is pushed or pulled or goes of its own motive power, there are certain things that it can be made to do and others that it cannot be made to do so long as its structure and equilibrium are intact. And however much one carriage may differ in details from others, it is like every other so far as obeying certain general laws of physics. In the same way spines may be grouped together in obeying certain physical laws, however much they may differ in detail.

A flexible rod, as for example a quadrilateral rod of rubber, in bending or twisting follows certain definite mechanical laws, and these laws can be formulated in advance by any one familiar with mechanics. A straight flexible rod can be bent in one plane without twisting, but if such a rod originally curved in one plane be bent in another it must twist. It must always do this and can do nothing else. When the top is bent forward and to the right while the lower end is held, the front turns to the left and always to the left. A fixed combination of twisting and sidebending exists for every position. From a mechanical point of view a pure twist may be produced in a straight flexible rod without causing side displacement. There is a turning of each part of this rod in the horizontal plane, which is spoken of mechanically as *shear*, but no bending of the rod as a whole appears. But let this rod be bent already in the antero-posterior plane, and torsion of such a rod inevitably causes side displacement when viewed in the antero-posterior plane.

This was demonstrated by experiment in a quadrilateral rod of sponge rubber one inch square and eight inches long and in a quadrilateral rod of lead thirty inches long. In the latter series of experiments the lower end of the rod was fixed in a vise and the twist given by a monkey wrench at the free upper end. In both series of experiments a twist to the left was followed by one curve, and a twist to the right by the opposite curve. These results were constant in both series of experiments.

The following experiments were undertaken on the human spine:

The spine of an adult of about forty and the spine of the cadaver of a boy eighteen years old were observed. The pelvis was firmly fastened to a box and the cervical region twisted to the right and left by the hands and by a long brass rod fastened to the third dorsal vertebra. A lateral curve always accompanied the twisting, and occurred always to the left when the twisting was to the right and to the right when the twisting was to the left. The curve was to the same side and followed the same rules as that observed in the lead and rubber rods.

Observations were then made on the living model. The model was a woman of twenty-five, a professional model, who was very flexible. With the pelvis fixed, active or passive twisting with the chin to the left produced a marked lateral curve to the right, with side displacement of the body to the right. Twisting to the right produced the opposite curve. The curves were of the same character and followed the same rules as those observed in the lead and rubber rods and the spine of the cadaver. In twisting with the chin to the left the lateral curve begins at the dorso-lumbar junction and sweeps gradually out, returning in the cervical region to practically the median line. The lumbar region apparently

FIG. 1. — COMPOSITE PHOTOGRAPH OF CADAVER.

Straight and twisted to left. The white line is a strip of cotton cloth nailed to the spinous processes. The straight white line was before twisting; the curved white line to the right is the twisted portion.

takes little part in the lateral curve. It appeared at first as if there were a slight left lumbar curve accompanying this right dorsal curve, but careful observation and measurement on the cadaver and model showed that there was but little if any lumbar lateral curve. There is but little movement of torsion in the lumbar vertebræ normally, so that, in spines comparatively normal, it can be readily seen that any phenomena of torsion would be shown above rather than in this section of the spine.

Torsion may be carried to a much greater degree in both model and cadaver when the spine is erect than when it is fully flexed. In the erect position 90° of rotation of the top of the column was possible in both, while in the flexed position only 45° was allowed. When twisting is done in the position of full flexion of the spine, the lateral curve is located higher up than when it is done in the simple erect position, and its lower limit begins at about the seventh or eighth dorsal vertebra instead of at the dorso-lumbar junction.

The backbone of a fish and the backbone of a cat when placed in corresponding positions behave in the same way as the rubber and lead rods, the living model and the human spine, and lateral bendings and torsion preserve the same relations to each other.

The result then of these observations is as follows:

(1) An active or passive twist with the chin to the left in model and cadaver is accompanied by a dorsal curve to the right with displacement of the trunk to the right. In the erect position this lateral curve begins at the dorso-lumbar junction. In marked flexion the lateral curve begins at the seventh or eighth dorsal vertebra.

(2) An active or passive twist with the chin to the right is associated with a left lateral curve and a displacement of the body to the left.

It may be objected that this lateral curve is merely due to the fact that the whole thorax is twisted to one side and that the dorsal excurvation is thus seen from its side rather than from its posterior aspect, thus giving the appearance of a lateral curve where none exists. Observations on the bodies of the vertebræ in the cadaver twisted in this way showed, however, that there was a displacement of each vertebra on the one below it, making a real curve.

FIG. 2. — ILLUSTRATION FROM FORMER PAPER.

Model twisting to left.

Regarding the human spine, then, as a flexible rod already permanently curved in the antero-posterior plane by the three physiological curves, two propositions follow:

(*a*) It cannot as a whole or in any part be bent to the side without twisting, as demonstrated in a former paper.[5]

(*b*) It cannot be twisted or rotated without acquiring a side bending.

[5] Mechanics of Scoliosis, Orth. Trans., vol. xiii, p. 251.

It is desired to formulate the last-named phenomenon of twisting or torsion for two reasons:

(1) To analyze lateral curvature by means of it to see if certain cases do not begin as a twist rather than as a side bending.

(*b*) To utilize twisting movements and manipulations in the treatment of lateral curvature.

In the application of conclusions drawn from such general laws to the treatment of scoliosis, it may be very properly objected that such laws may not apply to the movements of a twisted and stiffened spine. On the other hand, it may be true that the laws governing flexible rods, if properly studied and adapted to the especial conditions existing in such patients, may apply with especial force and may be one lacking factor in the more satisfactory treatment of scoliosis. Experiment alone will determine the fact. In any event no theoretical knowledge gained from the study of a flexible rod can be considered as applying to the human spine without confirmation by experiment on the living model and cadaver. The least objection to the application of such general laws to a specific spinal distortion would be found in beginning scoliosis, the so-called postural cases, but even here experimentation would be required to establish the similarity of behavior.

The application of these facts to the study of scoliosis is of interest. Since every side bending of the spine is necessarily associated with some degree of torsion, one would expect to find that in all cases of lateral curvature of the spine, however slight, the shoulders had twisted in their relation to the pelvis and that a line connecting two corresponding points in the shoulders was no longer parallel to a similar line in the pelvis.

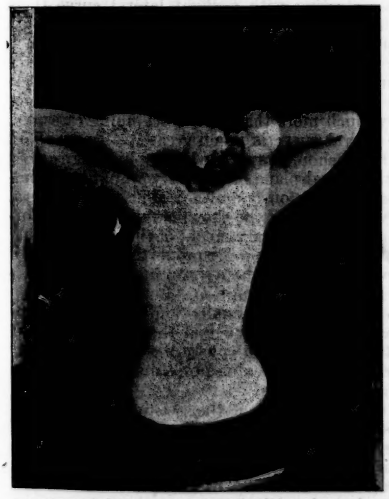

FIG. 3.—COMPOSITE PHOTOGRAPH OF MODEL. Twisting to left.

Looking down on a normal person in the erect position, the shoulders would not appear to be twisted with regard to the pelvis. In all cases of lateral curvature observed by the writer, such a twisting has been found. In cases of what appear to be at first sight purely lateral postural curves, beginning scoliosis of the kind where no rotation is supposed to exist, one will find on looking down on the patient standing at ease that the shoulders are noticeably twisted with regard to the pelvis and that one side of the shoulder girdle is carried forward and the other back. This is particularly noticeable in postural cases after they have been standing for a minute or two and muscular fatigue has commenced. Such patients if asked to bend forward until their trunk is horizontal (Adam's position) will appear to have no rotation or torsion present and it will also disappear in recumbency or suspension, but viewed from above in their natural standing position it is evident. It may also be demonstrated by placing long pieces of splint wood horizontally against the sacrum and the back of the chest above the spines of the scapulæ. This torsion is the inevitable outcome of every side yielding of the spine. But it is possible that the lateral curvature may have originated in a twist and that the side bending is secondary.

If a child holds the head naturally twisted, as is often the case, from some inequality in the vision of the two eyes or in the acuteness of hearing in the two ears, or from some similar cause, the spine will inevitably be twisted. Again, the contact of the condyles of the occiput and the articular surface of the atlas is generally best when the head is held otherwise than quite straight, which is an established anatomical fact. The twisted position of children at school in consequence of improper school furniture is another factor leading to the acquirement of a twisted position of the spine. These factors all tend to induce a twist of the spine, and a twist of the spine must in all cases be accompanied by a lateral deviation, to the right if the twist is to the left, and a curve to the left if the twist is to the right. This etiological factor has been left largely out of account in considering scoliosis.

Since the association of torsion and side bending of the spine is a constant one, as has been seen in the preceding experiments, it may be worth while to study scoliosis in terms of torsion. That is, to study the obliquity of the shoulders in a given case in the erect position to see whether the right or left shoulder is carried forward and knowing then the twist of the shoulder girdle with relation to the pelvis, to see with what lateral curve a right or left twist of the shoulder girdle is associated in the given case. In this way it is possible that some light may be shed on the origin of an individual case of scoliosis, and also possibly upon the general question of rotation.

In a former paper the following conclusions were reached by a series of experiments on the spine of the human cadaver and on the living model: [6]

[6] Lovett: Mechanics of Lateral Curvature. Boston Med. & Surg. Journ., June 14 1900.

"Lateral bending, then, in both cadaver and model in position of marked flexion is accompanied by torsion, and this torsion is in this position always in one direction, and is of the same type as the rotation seen in scoliosis; that is, backward on the convexity of the curve, or, in other language, the bodies of the vertebræ turn towards the convexity of the lateral curve. Various attempts were made to reverse this torsion while making side bendings in the flexed position by pulling the vertebræ apart, pressing them together, etc., but in all cases in both cadaver and model the type of torsion described above persisted." . . . "In the intact spine of the cadaver, therefore, and in the model, side bending in the extended position is accompanied by torsion of the vertebral bodies toward the concavity of the curve; in other words, the rotation is backward on the concavity of the curve, which is the reverse of the condition ordinarily seen in life in scoliosis."

Proceeding in the light of this to investigate scoliosis one finds that —

(1) A simple postural curve if acquired in the flexed position of the spine will show a twist which may be predicted in advance. In such a curve to the left the left shoulder will be carried back and the right forward because in such a curve the bodies of the vertebræ turn to the left as shown in a former paper.

(2) If it is a curve originating in the extended portion of the spine, that is, occurring in the lumbar region, the twist will be reversed, and the right shoulder will be carried back.

That cases of single postural curves commonly show a type of torsion that is the reverse of that seen in double curves has been noted clinically by Schulthess [7] and others (in one third of the cases of total scoliosis Jach. [8]) That is, in a left total curve the bodies of the vertebræ may turn to the right instead of toward the convexity of the lateral curve, which is to the left. This is explained by the existence of position (2) noted above. This in my experience seems to be the common type of torsion seen in the standing position in cases of total scoliosis of the postural type.

(3) If the curve originates in a twisting of the spine rather than a side bending the only twist that will cause a left curve is with the chin to the right and therefore the right shoulder is back.

In total left scoliosis, therefore, there are three conditions which make the shoulder girdle assume an obliquity with regard to the pelvis:

(1) A lateral curve to the left occurring in the flexed position of the spine with the left shoulder back.

(2) A lateral curve to the left occurring in the extended portion of the spine with the right shoulder back.

(3) A lateral curve to the left occurring as the result of a twisting of the spine with the face to the right, in which case the right shoulder is back.

Three reversed conditions exist, of course, for right total curves. If one takes these six conditions and rearranges them in terms of right or left shoulder back, one may construct the following table for the interpretation of simple total curves:

If the right shoulder is back it may be due to
(1) Right total curve acquired in flexion.
(2) Left total curve acquired in extension.
(3) Left total curve from twisting to the right.

If the left shoulder is back it may be due to
(1) Left total curve acquired in flexion.
(2) Right total curve acquired in extension.
(3) Right total curve from twisting to the left.

So far as the purely postural cases of lateral curvature are concerned, the twist of the shoulders should be easy to decipher when the relations of torsion and side bending are understood. But in the severer cases of scoliosis where there are two curves or even three curves, a new and confusing element, that of equilibrium or adjustment, comes in, which seems to have received little attention in the consideration of the mechanics of scoliosis. The element of equilibrium must modify the behavior of the spine, because in addition to being a flexible rod it must be considered a flexible rod with a sense of balance and equilibrium; not only is there continually an instinctive attempt when in the upright position to keep the head in the middle line of the body over the base of support, but to keep the shoulders parallel to the pelvis and the head looking approximately forward.

Were it not for this instinct of adjustment, one would expect that as the lateral curve increased the shoulders would twist more and more in their relation to the pelvis until in extreme cases of lateral curvature they might be twisted to an angle of forty-five degrees with the pelvis. Because starting with a slight lateral curve there would be a slight twist of the shoulders and with more lateral curve a greater twist — but such is not the case.

In cases of more advanced scoliosis the shoulders are also twisted in regard to the pelvis, but not very much more than in the beginning cases, yet the lateral curve is much greater. To go about with the shoulders twisted forty-five degrees out of the lateral plane of the body would be an impossible condition, and although in a slight lateral curve the twist of the shoulders might be proportionate to the lateral element of the curve, it could not increase in the proper proportion as the lateral curve increased without resulting in an impossible and disabling condition. Consequently somewhere between the shoulders and pelvis some compensation has occurred and the nature and seat of this compensation constitutes one of the most intricate and perplexing problems in the question of lateral curvature.

It would seem as if the twisting on a vertical axis shown in the prominence of the ribs on one side, known as the fixed rotation, in cases of scoliosis, were the result of this compensation. The shoulders must be kept roughly parallel to the pelvis and the head looking approximately straight ahead. To accomplish this parallelism of the

[7] Schulthess: Zeitsch. f. Orth. Chir., vol. vi, p. 399; Kirmisson: Rev. d. Orth., vol. vi; Hess: Zeitsch. f. Orth. Chir., vol. vi, p. 556.
[8] Zeitsch. f. Orth. Chir., 1892, 1.

shoulders and pelvis, compensating twists (rotation) must occur in both lumbar and dorsal region and they must be of an amount and character to keep so far as possible the top of the column pointing straight ahead. In the severe cases of right dorsal, left lumbar curve the left side will be prominent backward in the lumbar region, the right side backward in the lower dorsal region, but the axis of the shoulders again will be found backward on the left side. The instinctive sense of adjustment in keeping the atlas pointing in the same direction as the last lumbar vertebra is an important matter demanding compensating twists in a column which has once seriously curved to the side.

Rotation in severe lateral curvature, therefore, appears to be the result of the patient's instinctive effort to keep the shoulders square with the pelvis. A twist is necessitated by the beginning of every lateral curve, but this twist cannot carry the shoulder plane too far out of the pelvic plane. To get the shoulders back parallel to the pelvis a compensating twist must be added to the existing twist and the fixed rotation thus becomes the sum of the two. This is seen when one analyzes by the aid of the scheme furnished the condition where fixed rotation exists. The reading of the scoliosis in the light of the obliquity of the shoulders is not the same as in total curves of postural scoliosis, but apparently the reverse.

Fixed rotation is not, therefore, to be overcome by a simple untwisting, but must be regarded as a compound phenomenon induced by two twists, to be dealt with by local pressure in the usual way.

As to the therapeutic use of torsion of the whole spine, it is to be remembered that in the present treatment side bending and side pressure are practically the only unilateral or non-symmetrical movements used. Wullstein alone seems to have used torsion in forcible correction, but he has used it in connection with strong traction and as an accessory measure rather than to obtain its specific effect. Many complicated free standing movements involving torsion are used because they seem to place the spine in an improved position, but such movements when used are purely empirical and take but little account of the specific effect of torsion, which has never, so far as I know, been formulated or even studied from this point of view. Side bendings in the gymnastic treatment are of great value, but it must be remembered that side bending as such does not exist but always carries torsion with it. The trend of modern gymnastic treatment of late years has been toward laying more stress on symmetrical exercises and less on active side bendings.

The application of side force in the forcible correction of scoliosis has the theoretical and well-recognized objection that pressure must be communicated to the spine through the thorax. The ribs are movable at both ends and a certain amount of force must be expended on the ribs before acting upon the spine. Torsion, on the other hand, acts directly upon the vertebræ. Theoretically it has this point of advantage.

Torsion to the left with the spine erect causes, from the dorso-lumbar junction upward, a marked right dorsal curve and the trunk is carried to the right of the median plane. If the spine is flexed before being twisted the right dorsal curve begins higher up at the seventh or eighth dorsal vertebra and has the same character. Torsion to the right causes a left dorsal curve which may be distributed through the whole dorsal region or located in its upper half as may be desired.

Moreover, it is by no means clear that many so called postural cases of early lateral curvature do not have their origin in a twist of the whole spine rather than in a side bending, and that the apparent side bending is only the result of the twist. For such cases corrective twists would seem to be more rational treatment than corrective side bendings.

The therapeutic application of torsion is therefore plain. A right dorsal curve should twist or be twisted to the right, which should curve the spine to the left; should it be a high dorsal curve the twist should be given in full flexion of the spine. So far as the writer's experience goes, the therapeutic problem has been worked out only with regard to cases without fixed curves, where it has seemed to have a proper application and a distinctly good effect. With regard to cases with fixed curves it is not possible as yet to say what is its therapeutic value.

All that can be said at present is that torsion in the normal spine causes a distinct and uniform lateral curve. That postural cases of lateral curvature represent so slight a departure from the normal that rules governing the normal spine may be applied to them, as has been demonstrated experimentally. That postural lateral curves may apparently originate in (*a*) the flexed position of the spine; (*b*) in the extended position of the spine; (*c*) in twisted positions of the spine in which the lateral curve is only symptomatic of the twist. That in these cases torsion movements and passive torsions are of therapeutic value. And that in general the normal intact human spine behaves as would any flexible rod of similar curve, shape, and structure.

It is to be hoped that a further knowledge of torsion may enable us better to understand severe cases of scoliosis with fixed curves, and it is not unlikely that torsion movements and forced torsion may be of use in the correction of such cases.

A CRITICISM OF KLEMPERER'S WORK ON THE CONDITION OF URIC ACID IN THE URINE.[1]

FRANCIS H. MC CRUDDEN, BOSTON.

Laboratory of Physiological Chemistry, Mass. General Hospital.

WHEN hydrochloric acid is added to urine the whole of the uric acid does not immediately precipitate. His[2] showed that that which remained dissolved is in the colloidal state, and that con-

[1] Read at the Boston Society of Medical Sciences, May, 1908.

[2] His, W.: Die Harnsäure Ablagerungen des Körpers und die Mittel zu ihrer Lösung. Therapie der Gegenwart. Neue Folge, iii, 434, 1901.

tinued shaking of the solution with the precipitated uric acid will remove it. This author showed further that formaldehyde combined with uric acid forms a compound which is not a salt, and that if urotropin be administered to a patient, it decomposes, giving formaldehyde, which is found in the urine combined with the uric acid.

Basing his assumptions on the work of His, Klemperer,[3] at the last congress for internal medicine at Wiesbaden, said that the uric acid is found in the urine in four forms:

(1) The chemically dissolved part. By this he means the pure uric acid in ordinary solution.

(2) The physically dissolved uric acid. By this he means that portion of the uric acid in solution in the form of a colloid.

(3) The uric acid combined with bases.

(4) The uric acid in the form of an organic compound with some such body as formaldehyde.

The chemically dissolved uric acid, as he admits, is very little, for uric acid is soluble only in 40,000 parts of water. The uric acid organically combined has been shown to exist only after administration of urotropin or chinotropin, so that this can usually be neglected.

Klemperer then undertook to determine the relative quantities of free urea and uric acid as a salt. He first determined the total amount of uric acid in 100 c.c. of urine by Ludwig-Salkowski method, and then shook another 100 c.c. of the solution with an excess of uric acid for forty-eight hours, filtered, and determined the uric acid in the filtrate by the Ludwig-Salkowski method. He says that shaking the urine with excess of uric acid precipitates the colloidal uric acid and that the filtrate contains therefore only the uric acid combined as salt. By subtracting the uric acid combined as salt from the total, he obtains the amount of free colloidal uric acid.

In the first place, His did not show, as Klemperer says, that a part of the uric acid in urine is in a colloidal state. His showed simply that when the uric acid in urine is set free from its salt by hydrochloric acid complete precipitation does not take place at once, owing to a retention of some of the uric acid for a short time as a colloid.

In the second place, Voit and Hofman,[4] Camerer,[5] Zerner,[6] Mordhorst[7] and Ritter[8] have shown that when urine cools from the body temperature to the room temperature a chemical reaction takes place. Sodium acid phosphate reacts with sodium acid urate to form alkaline sodium phosphate and free uric acid:

$$Na\,H_2Po_4 + Na\,C_5H_3N_4O_3 = Na_2HPO_4 + C_5H_4N_4O_3$$

That is, the relative quantities of uric acid and urate change as the temperature becomes lower. Klemperer's determinations of the relative quantities of free and combined uric acid at the room temperature therefore do not show what he tried to show, that is, the relative quantities at the body temperature.

In the third place, Pfeiffer[9] tried to show the relative quantities of free and combined uric acid in urine by pouring the urine repeatedly through a filter covered with uric acid. He assumed that the free uric acid was precipitated upon the filter and that the uric acid as urate passed through. Ritter[10] repeated and explained the results of Pfeiffer. He showed that the amount of uric acid remaining after passing the urine through the uric acid filter depends upon a number of facts, but chiefly upon the relative amounts of alkaline and acid sodium phosphate present. Klemperer has simply repeated the work of Pfeiffer, using a slightly different technique to bring about his results, and therefore does not show the relative quantities of free and combined uric acid even at the temperature at which he carried out his determinations. From these experiments Klemperer concluded that a valuable part of the uric acid, usually, however, more than half, exists free and in the colloidal state in urine. Since the tendency of uric acid to become colloidal in pure water is but slight, he attempted to find what held the uric acid in a colloidal state in urine.

He carried out one experiment in which he found that the presence of urochrome, the coloring matter of urine, retarded somewhat the precipitation of uric acid from its salts by hydrochloric acid. From the result of this experiment the author concluded that urochrome is the agent which holds the uric acid in urine solution.

The precipitation of uric acid was retarded somewhat but not at all prevented by urochrome, so that if Klemperer's experiment is confirmed by other chemists we can conclude not that urochrome is the agent which holds uric acid in urine in solution, but that the slow precipitation of uric acid in Heinz' method of precipitation by hydrochloric acid may be due to the presence of urochrome.

A complete quantitative and generally applicable explanation of the behavior of uric acid when a urine cools cannot be given until more data are available. When urine cools from the body temperature to the room temperature the dissociation constants for the electrolytes present change. These constants, together with the

amounts of the different electrolytes, determine the concentrations of the various ions. If the change in equilibrium on cooling brings about an increase in the concentration of hydrogen ions these must combine with the negative uric acid ions from the sodium acid urate to form undissociated uric acid, for His[11] has shown that in a saturated solution of uric acid only 10% is dissociated. On account of the very low solubility of uric acid any undissociated uric acid formed will crystallize out.

In order to predict from its chemical composition whether on cooling the concentration of the hydrogen ions in urine will increase we must know, in addition to what is already known, at least the solubility and dissociation of uric acid at the body temperature and the dissociation of alkaline and acid sodium phosphate in solutions of different strengths at the body temperature and at the room temperature. We hope to determine these data and study the subject in detail. It seems probable that except the sodium salts the other bodies in the urine have only a lesser influence on the precipitation of uric acid.

Medical Progress.

PROGRESS IN OTOLOGY.

BY PHILIP HAMMOND, M.D., BOSTON.

(Concluded from No. 5, page 129.)

MASTOID DISEASE.

DURING the year several writers, in speaking of the mastoid operation, point out that the great danger consists in allowing the case to be neglected, and delaying operation too long.

Bliss[33] states that acute mastoiditis is a dangerous condition, and owing to the irregularity of its symptoms in different cases the question as to when one should operate is often veiled in uncertainty. Certain indications, however, continuing for several days, may be relied upon as of value in guiding the surgeon to favor an opening of the cells: First, steady, persistent pain over the mastoid process in the region of the antrum; second, the existence of edema; third, the temperature of the patient. In operating we should always aim to secure free drainage of the antrum. Although mastoiditis will, in some instances, develop during the most carefully conducted treatment of an otitis media, its prevention is undoubtedly very often due to proper care of the affected middle ear. It is especially urged that all acute inflammatory conditions of the ear be given early and appropriate treatment as the only safe means of averting a train of complications which may end in the patient's death.

Among the observations regarding temperature in mastoiditis during the year are the following: The writer[34] placed on record certain cases showing that the absence of temperature was of absolutely no importance as an indication of the necessity for operation.

In a study of a hundred cases, Harris[6] found that after operation (1) a moderate amount of temperature is customary; (2) the cause of it has not yet been definitely determined; (3) without other symptoms it is devoid of significance, and should not be a source of anxiety.

Holt[35] reports a case in which, following the ablation of both mastoids, a young woman had remarkable variations of temperature, ranging from as high as 114° to 94. These extreme variations were noted at the same time in different parts of the body. It was the opinion of those who saw her that the condition was due to hysteria.

Goldstein[8] regards an infection of the ear during an attack of grippe as distinctly different from an ordinary acute catarrhal otitis media, in that the invasion of the ear and mastoid are practically simultaneous, and active treatment must be at once instituted to enable our patients to avoid mastoid complications. Stress is laid upon the importance of early and free incision of the drum membrane, and it is urged that conservatism be employed in cases where tenderness of the mastoid appears, as many of the symptoms of mastoiditis are accompaniments of influenza.

On the other hand, Dench[36] again asserts his belief that it is a most dangerous procedure to use the cold coil to abort the inflammation within the mastoid, on the ground that it masks symptoms and gives one a false sense of security. He tries it, however, in cases where he sees the patient from the very inception of the disease, combining with it free drainage of the tympanic cavity. At the end of forty-eight hours, if the case is not progressing toward recovery, operation is indicated.

Whiting[6] calls attention to the cells at the base of the zygoma, believing that they are the cause of many cases of recurrent mastoiditis, and advocating their removal in all operations in this vicinity. Dench agrees with him, going even to the extent of advocating the removal of all the pneumatic cells in the occiput.

Injuries to the facial in tympanic exenteration is considered by Randall,[37] who has carefully outlined the course of this most important structure. In actual work it is not difficult to locate, as we can nearly always find the oval window, and we know that the upper margin of this niche is formed by the prominent facial canal. It goes forward but a few millimeters from this spot before disappearing into the depths of the petrous bone. Backwards from the oval window the nerve curves downwards, leaving the bone at the stylo-mastoid foramen. It is harder to recognize the nerve as we approach it through

the mastoid, but even here there are unmistakable bony landmarks which should indicate its presence to us. There is always the polished bony prominence on the inner wall of the antrum, which marks the protuberance of the horizontal semi-circular canal and the downward curving portion of the facial. A careful description of the organs adjacent to the middle ear is also given by Schmitt [38] and Stein.[39]

In the after-treatment of the radical operation, Muehlen [40] closes the retro-auricular opening primarily. The posterior wall of the canal is slit, and the first packing of iodoform gauze remains for six days. Another tampon is then loosely introduced and allowed to remain for two or three days. Eight days are allowed for the flaps to grow into their new places. As soon as this is accomplished, all packings are omitted. Irrigations with warm water are then used daily. He claims to experience very little trouble from excessive granulations forming in this method of treatment.

A case of cholesteatome of the middle ear with loss of memory is recorded by Packard.[41] The patient was twenty-three years old, and had had chronic suppuration for twelve years. Complete relief followed mastoid operation.

THROMBOSIS OF THE LATERAL SINUS.

In an article reviewing the history of this operation, Dench [6] states that the thorough mastoid operation was not commonly performed until within the past ten years. At the time when it was customary to simply drill a small hole into the antrum, a perforation into the lateral sinus was looked upon as being almost necessarily fatal. Then, following the teachings of Schwartze and Gruening, more radical measures were adopted even in all acute operative cases, and practically all of the cellular structures of the mastoid were removed. As soon as surgeons became bold enough to do this, it was found that exposure or wounding of the lateral sinus became divested of the terror which it had formerly inspired, and affairs progressed so that from becoming an unwished-for accident, it was commonly done as a prophylactic measure.

Dench [42] most emphatically believes in early operation in all suspected cases, and states that he has operated on twenty-two cases, with but two deaths. One of these was from a septic pneumonia, and the other from a nephritis induced by the anesthetic. In only four of the cases was it necessary to ligate the internal jugular, and all of these recovered. He believes that prompt surgical interference of the most radical kind is the only safe course. Ligation is demanded only in those cases in which the clot cannot be wholly removed from the sinus, and where there is undoubtedly a certain amount of infected material left in the venous canal.

[38] Am. Journ. Med. Sci., April, 1903.
[39] Laryngoscope, December, 1902.
[40] Arch. of Otol., April, 1903.
[41] Med. News, March 8, 1902.
[42] Am. Journ. Med. Sci., May, 1902.

Lederman [43] reports a case in which, after operating and tying the internal jugular, there was a relapse, with reinfection of the vein. This was again operated upon, and the patient made a good recovery. Lederman believes that the diagnosis must be based mainly upon the appearance of pyemic symptoms accompanying an acute or chronic purulent disease of the middle ear. He considers the most prominent symptom to be the rigor accompanied by profuse perspiration. He places little reliance upon the cordlike sensation in the vein, and has not been able to detect it, but considers as of more importance the presence of tenderness along the anterior border of the sterno-mastoid muscle. Opening or tapping the sinus should be avoided if possible, as cases of infection with fatal results have been reported by Linser [44] and others.

OTHER INTRA-CRANIAL COMPLICATIONS.

The importance of thorough operation in cases of mastoiditis complicated with cerebral symptoms is shown by cases reported by Broca and Laurens,[45] and Massier.[46] Several surgeons and neurologists who saw Broca's case pronounced it one of cerebral abscess. There were frequent chills, paresis of an arm, some aphasia and disturbances of vision. Massier's case is equally striking. Complicating the otorrhea there was violent headache and complete paralysis of the left arm with loss of movement of both legs. Here also a diagnosis of abscess of the brain was made. The radical operation in both cases revealed a meningitis due to infection from the ear, and the result was a complete disappearance of the symptoms.

Lewis [47] reports a case of chronic suppuration in which a cessation of the discharge from the middle ear was followed by chills, sweating and a rise in temperature. There was partial facial paralysis and amnesic aphasia, but no other paralyses and no optic symptoms. At the operation the mastoid and middle ear were found to be filled with pus, and an extra-dural abscess was found beneath the squamous portion of the temporal bone. Gauze drainage was used, and the patient made a good recovery.

Jack [48] succeeded in saving a case of brain abscess following suppurative middle ear disease. The patient had had a discharge from the left ear for three years. There had been frontal headaches for six weeks, and there was tenderness of the mastoid. The mastoid was opened, and necrosed bone and pus removed. The lateral sinus was exposed for an inch, but as the dura was normal in color, and there was no bulging, it was not opened. The patient improved for a time, but on the eighth day passed into coma. The wound was opened up, the dura opened, and several ounces of pus and necrotic tissue removed. Good recovery.

[48] Bost. Med. and Surg. Journ., Dec. 26, 1901.

Braunstein [49] suggests the extreme importance of lumbar puncture as a means of diagnosis in intra-cranial complications of otitis media. In a total of forty-eight patients he has made it sixty-seven times to establish an indication for operation by exclusion of diffuse purulent meningitis, or to establish an indication for omitting operative interference by proving the presence of the above form of meningitis. The fluid removed by lumbar puncture is turbid, or even purulent in inflammation involving the cerebrum, spine and meninges. This turbidity may be due to chemical changes, or to an increase of leucocytes and admixture of pus corpuscles and bacteria. In tubercular meningitis the fluid may be clear, although containing bacilli. In uncomplicated cerebral abscess the fluid is clear, but the amount increased in quantity.

CHRONIC CATARRH OF THE MIDDLE EAR.

After a thorough test of nearly all the new methods of treating this disease, Randolph has failed to find the agent which can be said to be pre-eminently satisfactory. He believes that catheterization is the most satisfactory of the mechanical methods. Although he does not believe in the value of internal medication in this disease, he admits that he has seen cases distinctly benefited by thiosinamin in half-grain doses three times a day. In larger doses it is apt to produce vertigo. It seems to be especially valuable in the treatment of tinnitus aurium. It is claimed for this drug that it causes absorption of cicatricial tissue. There is an increase in the amount of the white blood corpuscles while the drug is being taken.

Snow [6] states that local intra-nasal factors must be taken into account before embarking upon the treatment of catarrhal deafness, but the mistake is often made that they are the whole cause, and too much benefit is expected from the correction of abnormalities there. He points out that there are many general diseases underlying the deafness, and that, if unrecognized, these prevent the fullest returns from thorough operations upon the nose. Disturbances of the skin, liver, stomach and other organs give rise to inflammatory changes in the head membranes. Much of the trouble to which we are subject is due to coddling and living in overheated apartments.

In a consideration of this subject, Harris [6] concludes:

(1) That we have made very little progress in treating chronic catarrh of the ear.

(2) That our chief success to-day rests in our ability in setting aside the producing nasal catarrh.

(3) That tubal therapeutics and pneumo-massage are at the best too often of temporary benefit and in the hands of some even of decided harm.

(4) That all we can promise with safety is to check the deafness.

(5) And that prophylactic measures are of the greatest value, especially the removal of the ever-present adenoids.

Hopkins [50] advocates the use of super-heated compressed air in the treatment of chronic catarrhal otitis media, as does also Oaks.[51] The former has obtained gratifying results in cases not benefited by other forms of treatment. He believes, however, that as an exclusive form of treatment it is rarely of much value, but that it gives the best results when used in conjunction with the recognized forms of treatment. He ascribes its beneficial effects on the ossicular chain to the fact that the joints have a very superficial covering.

Watson [52] has administered bone marrow internally in the treatment of chronic aural catarrh, and he reports twenty cases in which this was tried. His theory is that bone marrow produces an internal secretion of vital importance to the economy, and that this substance is a prophylactic against the action of various bacteria.

Electrolysis of the Eustachian tube is mentioned by many writers, none of whom obtain the brilliant results at first reported by Duel.

Melzi [53] claims to have relieved various obstinate chronic cases by the passage of a rubber sound into the Eustachian tube. He considers this to be a measure at once simple of application and devoid of danger.

Blake [11] believes that the various forms of pneumatic massage apparatus have greatly increased the number of patients with tension anomalies of the sound transmitting mechanism, because of the fact that they can be easily applied and in many cases at first seem to aid the hearing. He considers that unduly forcible inflation of the middle ear may cause extensive trouble by stretching the drum membrane. He is inclined to favor exploratory tympanotomy in cases of chronic non-suppurative inflammation of the middle ear, when treatment does not ameliorate the condition.

Harris [54] thinks the prognosis rather poor in most cases of tinnitus aurium, yet the results of treatment are not so unfavorable as is commonly supposed. In some cases treatment is directed to the ear locally, in some to the Eustachian tube, and various operations around the turbinates apparently affect the continuance of the noise.

Pynchon [11] continues to advocate pneumatic massage for various affections of the ear. By means of a special electric pump which he has devised for the purpose, he claims to be able to overcome the objections to the use of the mechanical masseur, as he is able to regulate absolutely both the amplitude of vibration to be applied to the drum and the speed. As a result of his observations he concludes that slow vibrations (30 to 90) are generally best adapted to middle ear troubles; that more rapid vibrations

(300 and over) have a more pronounced effect upon the labyrinthal nerves, and that improvement, of middle ear conditions will have a favorable effect on the labyrinth in those cases in which disease of both the middle ear and inner ear co-exist.

Randall [55] believes that no harm will result from a careful use of Seigle's otoscope with a rubber bulb or of massage with the finger tip, but does not think that this applies to the mechanical vibrators.

Schwabach [56] reports as a result of tests of the therapeutic value of vibratory massage of the drum head an improvement in only 4.9% of cases of sclerosis of the middle ear, and is not inclined to look upon it with favor.

A new form of massage has been suggested by Hamm,[57] who believes that the membranes can be softened by making the pressure stronger, at the same time lengthening its duration. This he accomplishes by seating the patient in a cabinet, in which he produces the requisite atmospheric conditions.

Bates [58] goes to the extent of advocating the removal of the posterior wall of the bony canal in intractable cases of chronic catarrhal deafness. He reports good results following this method, the main objection being the length of time required.

OTITIS MEDIA INSIDIOSA, OR STAPES FIXATION.

During the past few years improved methods of decalcifying, embedding and staining sections have materially advanced our knowledge relative to this most important disease of the ear.

The idea which prevailed for many years was that an interstitial inflammation of the mucous membrane of the tympanic cavity initiated the so-called sclerosis, which by extension involved the chain of ossicles and the oval and round windows. Clinically there was a high degree of deafness with open Eustachian tube and normal appearing drum. It was considered that the membranes closing the foramina were directly responsible for the deafness, by mechanically obstructing the sound conduction.

Hartz [6] points out that microscopic sections reveal the location of the trouble as due to hyperplasia of the bony elements of the capsule of the labyrinth. This osseous process may be located simultaneously in the cochlea and the ossicular chain, and may also extend to the semi-circular canals. Politzer suspected years ago that capsulitis labyrinthi often began at an early age, progressing slowly toward complete fixation of the stapes. Bony deposits are most noticeable in that part of the ear which has the greatest functional activity, namely, around the base plate of the stapes. As to treatment, Hartz advises internally such medicinal agents as will promote absorption, as iodine, mercury and phosphorus, but admits that the results are negative. Thyroid extract has apparently given good results in the early stages. Politzer strongly recommends large doses of potassium iodide. Mechanical treatment, as carried out by means of the various masseurs, apparently aids the patient temporarily, but carried to excess can only result in harmful stretching of the membrana tympani, as pointed out by Blake.[6] This stretching occurs in the upper posterior quadrant of the membrana, and gives rise not only to an increase in the deafness, but may also cause a most annoying tinnitus. Surgical measures, such as stapedectomy, are followed by temporary relief only.

LABYRINTH.

Involvement of the labyrinth following or during an attack of the mumps is one of the rarer complications of the disease, chiefly important because of its serious prognosis.

Texier [59] gives a *résumé* of the literature of the subject, stating that the onset is sudden, somewhat resembling Meniere's disease, and the deafness permanent. It may involve one or both ears. The lesion is thought to be in the labyrinth.

Félix [60] insists that we should carefully examine all cases of labyrinthine deafness for evidence of syphilis.

In syphilis of the labyrinth Dench [6] uses pilocarpine internally in conjunction with hypodermic injections of mercury. It may be necessary to give it for two or three weeks before its effect will be noticeable.

Bacon [6] calls attention to the fact that pilocarpine is a marked depressant, and great care must be exercised in its use.

Scheyr [23] reports the case of a patient with involvement of the labyrinth following the ingestion of salicylate of soda for rheumatism. On the sixth day she was taken with very intense headache, vertigo and tinnitus in both ears. Although the medicine was at once stopped, the vertigo was persistent. The drums showed nothing abnormal. Bone conduction on the left was completely lost. Treatment apparently produced no relief.

TREATMENT.

Gruening lays stress upon the point that the ability to inspect the drum membrane is the first requisite for the general practitioner in the treatment of ear diseases. Meierhof [61] also states that very few cases require major operations where the patient has had the benefit of early expert treatment.

Among the new drugs which have been used during the year is thiosinamin, which has been experimented with by Beck [37] as a solvent for cicatrices in the Eustachian tube and middle ear. It is stated by various authorities that

[55] Journ. A. M. A., Aug. 31, 1901.
[56] Arch. of Otol., August–October, 1901.
[57] München. med. Woch., Feb. 5, 1902.
[58] N. Y. Med. Journ., May 3, 1902.
[59] Rev. heb. de laryngol., d'otol., etc., November, 1902.
[60] Ann. des malad. de l'oreille, du larynx, etc., December, 1901.
[61] Arch. of Otol., February, 1902.

this drug has the property of producing a local reaction when injected into any portion of the body where there is poorly nourished tissue, especially cicatrices or old inflammatory structure. As used by Beck, a 15% solution of thiosinamin is prepared and injected between the scapulæ or into the arm subcutaneously, starting with ten drops once a week, in some cases twice a week. This dose is gradually increased until an ordinary hypodermic syringeful is used each time. This treatment is combined with ordinary local measures, and nasal obstructions and the general health of the patient carefully looked after. As the result of treatment in fourteen cases, he concludes, first, that the injection of thiosinamin without mechanical treatment did not improve the condition, except to relieve the tinnitus somewhat; second, that with the aid of electrolysis and injection of thiosinamin the simple bougie could be passed with much greater ease, and inflation was accomplished with greater facility after a short time than was experienced in cases where these were not used; third, that all the cases treated with thiosinamin and electrolysis improved in from two to eight months in all respects — hearing, tinnitus aurium, general condition, etc.; fourth, that before using the thiosinamin careful inquiry should be made for possible contraindications for its use, such as co-existing chronic tuberculosis, malignant tumors, scars which support the abdominal organs such as are formed after laparotomy, etc.

Richards [6] has for several years been using soluble bougies for the relief of earache in children. They contain carbolic acid, opium, cocaine and atropine, and are to be inserted into the external canal, where they become liquefied by the body temperature.

Lederman [62] reports that Argyrol has been found satisfactory in the treatment of granular conditions of the ear. It is used in solutions varying in strength from 5 to 50%, and no irritation was noticed even from the strong solutions.

Static electricity has been used in the treatment of tinnitus by Drs. Bayer and Penninckx.[63] They apply the blunt point of the metallic conductor to within about 1 or 2 cm. of the tympanic membrane. The production of sparks should be avoided. They state that they have never seen any harm come from the employment of the method.

Stoker [64] records four cases of deafness with tinnitus, which he treated by pumping into the Eustachian tube ozone, which he generated from the electric current by means of a Ruhmkoff coil. In all the cases there was improvement of both hearing and tinnitus.

In using Lucae's pressure probe König [63] dips the little cup on the end into melted paraffin. When used in this way the massage is less painful.

Reports of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

TWENTY-FIFTH ANNUAL MEETING, WASHINGTON, D. C., MAY 12, 13 AND 14, 1903.

(Concluded from No. 5, page 132.)

SECOND DAY — (*concluded*).

DISEASES AND TREATMENT OF THE SPHENOIDAL CELLS, WITH REPORTS OF CASES.

DR. ROBERT C. MYLES of New York read this paper, first showing a number of special instruments for work on the sphenoidal and ethmoid cells. He called special attention to the frequent irregularities and anomalies of size and position of the sphenoid cells, and showed a very fine wet specimen of half the skull, with the spheno-palatine and internal carotid arteries injected, the former crossing the field of operation, the latter lying close against the very thin inner wall of the sinus. He considered disease of the sphenoid cells much more common than usually reported. He advised the removal of the posterior end of the middle turbinate, when necessary, as a diagnostic measure, and when diagnosis is made, advised making a free opening in the anterior-superior wall of the sinus, close to the septum.

OBSERVATIONS ON THE DIAGNOSIS OF NASAL SINUSITIS.

DR. WALTER J. FREEMAN of Philadelphia presented this paper. In regard to the maxillary antrum he referred to the frequent failure of trans-illumination as a test for disease of the antrum, and noted the fact that when only one antrum was affected it was usually on the narrower or more obstructed side of the nose. In cases of inflammations of the antrum, acute or chronic, he considered the presence of pus flowing over the upper surface of the posterior end of inferior turbinated bone as the most frequent and the most certain sign. Intermittent cacosmia was a frequent and valuable sign. If any of the molar or bicuspid teeth were capped, or were at all discolored, they should be very carefully examined.

The author claimed to be able to wash out the maxillary sinus, in most cases through the natural opening, and showed a slender, flexible hard rubber canula for the purpose.

In regard to the frontal sinus he mentioned the usual train of symptoms, but gave special weight to the appearance of pus in the upper angle of the vestibule, claiming that when persistent, this sign was practically pathognomonic.

As to ethmoid disease, the author expressed great scepticism as to the frequency of its occurrence and the number of cases reported, and thought that most of them were undiscovered cases of antrum, frontal or sphenoid suppuration. As to the sphenoid cells, the author seemed to think that excepting by process of exclusion or by opening the sinus by an external operation, a definite diagnosis was almost impossible.

DR. BRYAN of Washington, in discussion of the papers on sinus disease, spoke of the frequent anomalies occurring in all of the sinuses, and showed a specimen in which the sphenoidal sinus was very large and extended far down into the pteregoid process. He expressed disapproval of the maxillary route for operation on the sphenoid sinus.

DR. MAYER of New York claimed that it was very seldom that the antrum could be washed out through the natural opening, but that it must be punctured through the outer wall of inferior meatus, a very simple matter.

He thought that the maxillary antrum route to the sphenoid was the best one, and would be the operation of the future.

DR. KING of New Orleans considered the Caldwell-Luc operation the best for most cases of frontal sinus disease; objected to the Kuhnt operation on account of the great deformity resulting; reported two cases done by a combination of Kuhnt and Luc operations with good results, and called attention to the frequent temporary infra-orbital neuralgia following the Caldwell-Luc operation.

DR. GLEITSMANN of New York spoke of a case of secondary hemorrhage, and said that he used liquid vaseline to loosen up the packing in all cases, thereby, he thought, lessening the tendency to hemorrhage when the packing was removed. He also spoke of the distance to which an instrument must be passed into the nose to reach the sphenoid sinus. This he had found very variable, in some cases 3½ to 4 inches; in others 5½ to 5¾ inches.

DR. LUC, in closing, said that he had not found any great difficulty in working through the floor of the frontal sinus; that the object of the operation was the obliteration of the cavity of the sinus, and that often it was a choice between complete success in that respect and a considerable degree of deformity, and when necessary we must choose the latter. He had found that the uprising of the fatty tissue of the orbit through the wound in the floor of the sinus helped to obliterate the cavity and to reduce the deformity.

As to the drainage opening into the nose it must be large enough to allow the finger to go up through the nose into the cavity of the sinus.

COMPLETE REMOVAL OF LEFT VOCAL CORD FOR MALIGNANT DISEASE. PRESENTATION OF THE PATIENT.

DR. WALTER F. CHAPPELL of New York reported a case as above. The patient had a small malignant growth on anterior end of left cord, with marked infiltration of whole larynx. In October, 1901, the case was operated upon, with preliminary tracheotomy, thyrotomy and total removal of left vocal cord and immediately adjacent infiltrated tissue. There was good recovery and there has been no recurrence to date. The patient has a husky voice, but articulates plainly and without effort. The author urged early diagnosis and early radical operation.

DR. MYLES of New York spoke of the relative value of the clinical and the microscopical aspects of these cases, and said that in many cases of removal with no recurrence, where the microscopical findings have shown malignancy, he often felt inclined to doubt the results of the microscopical examination.

PERICHONDRITIS OF THE LARYNX FOLLOWING TYPHOID FEVER, WITH REPORT OF A CASE.

DR. EMIL MAYER of New York read this paper. He stated that laryngeal inflammations due to typhoid fever were not very rare, and said that they were frequently important and valuable as a diagnostic point, as they may occur very early in the course of the typhoid. Marked stenosis of the larynx, the author said, was very rare; the ulcerations, when present, were usually caused by the ordinary pyogenic bacteria, and very rarely by the typhoid bacillus itself.

His conclusions were that the best general plan of treatment was early tracheotomy, with subsequent dilatation and intubation.

DR. DELEVAN of New York said in discussion that the condition was a rare one, and in about 94% of the cases was fatal.

He felt that the general consensus of opinion was that dilatation was usually not successful and that the use of O'Dwyer's tubes was the only rational treatment. He urged the importance of thorough care and cleansing of the upper air passages in typhoid, to prevent if possible this sort of complication.

DR. SIMPSON of New York advised the introduction of the tubes, under ether, as in that case we could use a larger tube and could probably use O'Dwyer's tubes and not have to use the Schrotter tube.

(*a*) A CASE OF EARLY APPEARANCE OF PARALYSIS OF THE VOCAL CORDS, IN MEDIASTINAL TUMOR.
(*b*) A CASE OF SARCOMA OF THE NASO-PHARYNX.

DR. WILLIAM K. SIMPSON of New York reported these two cases.

In the first one the author followed the course of the case in detail for several months, noting particularly the progress of the paralysis of the cords, the aphonia and the cough, and ending in the death of the patient. He then noted the findings at the necropsy, these being a large cancerous mass involving the mediastinal glands, and completely filling the posterior mediastinum, carcinoma of the left lung, carcinoma of the retro-peritoneal glands and an acute lobar pneumonia.

He presented the case to put on record an instance of complete bilateral paralysis of the vocal cords, which is the rarest form of laryngeal paralysis; to emphasize the early appearance of laryngeal paralysis as an indication of intra-thoracic pressure, which is often observed in unilateral paralysis and often antedates any positive physical signs in the chest, and to note the difficulty in exactly defining the lesion in such cases, even when autopsy has shown it to be very extensive.

(*b*) In the case of sarcoma of the naso-pharynx, the patient was twenty-seven years of age; there was a large mass nearly filling the naso-pharynx, bleeding easily and looking like an ordinary adenoid growth, and giving no symptoms excepting moderate obstruction to nasal breathing and some trouble in one ear, which latter cleared up under local treatment, the patient for a time refusing operation upon the mass in the naso-pharynx.

Later he had frequent and copious nasal hemorrhages, and consented to operation. The mass was removed in January, 1903, by curette, under cocaine and adrenalin, with very little hemorrhage. There had been no recurrence to date, and the patient's general health was much improved.

DR. THEISEN of Albany reported a case with adductor paralysis and dyspnea, upon which he did a tracheotomy for the relief of the dyspnea. A radiograph was taken later, and from that and other symptoms the diagnosis of an aneurism was made. After death, at the autopsy, a large mass was found behind the trachea and pressing upon it, and both the recurrent laryngeal and pneumogastric nerves were involved in the mass.

NOTES ON CASES OF NASAL SARCOMA, WITH EXHIBITION OF PATHOLOGICAL SPECIMENS AND MICROPHOTOGRAPHS.

DR. J. PRICE-BROWN of Toronto presented this paper and gave notes of several cases of from one and one-half to eight years' standing without recurrence since operation. He advised removal of these growths in all cases, by snare if pedunculated, and by snare, electric or cold, and forceps and scissors when sessile, taking the mass out piecemeal and at many sittings if necessary rather than doing an open external operation, which caused much deformity.

He found the hemorrhage severe in all his cases, but fairly easily controlled by adrenalin and packing, and had had no secondary hemorrhage. He urged early diagnosis and operation, because then could operate more easily intranasally, and also of course would have less chance of recurrence.

DR. SHURLY of Detroit said that he did not yet feel hopeful of permanent good results in these cases. All that he had seen had recurred.

DR. CLARK of Boston also felt discouragement as to the final results. He thought that they should be kept under observation for a longer period before being reported as cured.

DR. HARRIS of New York said that the hope of a final cure was a misplaced hope so far. He said that the prognosis rested somewhat upon the locus of the growth: if on the septum and pedunculated, so that the operation could be intra-nasal, the prognosis was good; but if diffuse and in the ethmoid region, it was bad. In the latter location he thought that the external operation was better than intra-nasal attempts.

DR. MYLES of New York urged early and radical operation. He spoke of finding in dissections of normal cases a small cartilage, extending from the basilar process to the sphenoid bone, and suggested this as the possible starting point of these sarcomata. He had noted also that in any case of tumor of this region, with a microscropical verdict of sarcoma, if it could be tided over to thirty or thirty-five years of age, it usually atrophied and disappeared — possibly due to the atrophy of this cartilage.

DR. LELAND of Boston urged the importance of early operation, as most of these growths were fibrous and benign early in their history, becoming sarcomatous and malignant later.

DR. GLEITSMANN of New York agreed with the protests against too early reports of cases as cured, but still thought that such protests should not be allowed to discourage operating, for even if it does not cure, the operation will frequently prolong life for one or more years and give relief from pain, and should therefore be done.

ADDITIONAL NOTES UPON THE TREATMENT OF NASO-PHARYNGEAL FIBROMA.

DR. D. BRYSON DELEVAN of New York in this paper called attention to the high rate of mortality of the formidable methods of the older surgeons for the removal of these growths, and presented an extensive series of cases to prove the superiority of operation through the natural passages.

His statistics showed that the mortality rate of such preliminary operations as resections of the superior maxilla and of the nose and the like was very high, while removal through the natural passages by such methods as evulsion, or cold snare, or electrolysis, or galvano-cautery-snare, gave most brilliant results. A brief summary of 135 cases was as follows:

Fibroma	*Total Cases.*	*Cured.*	*Died.*	*Recovered.*
Preliminary Operation	27	16 (59.25%)	7 (25.9%)	4 (15.4%)
Evulsion or Snare thro' Natural Passages	41	39 (95%)	2 (5%)	0
Electrical Methods thro' Natural Passages	66	66 (100%)	0	0

He noted the excellent work done in this field by the late Dr. Rufus P. Lincoln and by Dr. E. Fletcher Ingals of Chicago. He felt that the older method by preliminary operation would soon become obsolete, and that the newer methods by intra-nasal route would be the only operations of the future.

A METHOD OF RAPID EXTIRPATION OF NASO-PHARYNGEAL FIBROMATA, WITH REPORT OF CASES.

DR. GORDON KING of New Orleans read this paper. He said that he had noticed that these growths continued to increase up to twenty-five or thirty years of age, and then generally atrophied. He had found that igni-puncture and x-rays and other methods of trying to make the tumor shrink up were unavailing, and he felt that radical and complete extirpation was the only satisfactory plan of treatment. The author noted three special difficulties in operating:

(1) That of getting at the tumor.
(2) Hemorrhage during operation.
(3) Suffocative pneumonia.

He examined the growth digitally, and if it was pedunculated the operation was a simple one, merely snare it off; if sessile, he then operated with the finger in the naso-pharynx as a guide, and cut out the mass with long, strong scissors passed through the nose. The hemorrhage, though troublesome and sometimes dangerous, was readily controlled by pressure, and once stopped did not tend to recur. He advised preliminary tracheotomy.

DR. MYLES of New York reported a case which involved several operations both intra-nasal and external with recurrence after each one, but which finally after the patient reached twenty-eight years of age disappeared spontaneously.

THE REMOVAL OF CICATRICIAL CONTRACTIONS OR OBSTRUCTIONS OF THE NOSE BY THE SUBCUTANEOUS PLASTIC METHOD.

DR. JOHN O. ROE of Rochester read this paper, and demonstrated several of the delicate operations by means of plates, and showed a number of special instruments.

After speaking at length of the usual causes and usual older methods of treatment, he said he had found the latter unsatisfactory in many cases. Then as showing his present method he said for anterior contractions of the external opening of the nostril he made a crescentic incision denuding the surface of the contracted or filled-in portion, leaving the skin attached at one end as a long flap, then after excising the mass in the angle of the nostril he used the flap to cover in the raw surface thus exposed, or as much of it as the flap could cover, leaving the small balance to granulate.

In many cases of internal "bands" he found it possible to dissect off the mucous membrane covering the upper surface of the band, and then after excising the mass of the band to cover the raw surface left with this flap of mucous membrane.

For collapsed alæ he recommended making two incisions into the lateral shield cartilage (on the inside of the nostril) at an angle with each other, excising the wedge of cartilage between them and then suturing the edges of the cartilage incision together, thus causing the cartilage to bulge outward and carry the ala with it and hold it there.

DR. MAYER of New York suggested the use of the cargile membrane after operations in the nose which leave a raw surface exposed.

(*a*) FACIAL NEURALGIA DUE TO DISEASE IN NOSE AND ANTRUM.

(*b*) IMMEDIATE TRACHEOTOMY FOR FOREIGN BODY, WITH COMMENTS ON THE CASE.

DR. WM. PEYRE PORCHER of Charleston, S. C., read this paper (*a*). He noted that in very few instances in medical literature had any connection been observed, claimed or proved between facial neuralgia and conditions in the nose. He claimed, however, that it is the rule rather than the exception in these cases that the neuralgia is a reflex neurosis due to pressure or inflammation in the nose or antrum, and he deprecated the many extensive operations on the nerve trunks and ganglia, and upon the teeth, when generally relief of the difficulty in the nose or antrum would cure the neuralgia.

Dr. Porcher then detailed several cases with the usual train of symptoms in which operations in the nose relieving pressure or obstruction stopped the neuralgia.

(*b*) He also reported an interesting case of foreign body in the larynx and trachea of a child eight months old, with immediate tracheotomy and recovery. The foreign body was a small green pine burr, which, after unavailing attempts to extract it from above, fell through into the trachea, from which it was extracted by tracheotomy.

DR. ROE of Rochester reported two cases of facial neuralgia cured, one by removal of a large spur from one nostril, the other by removing an irritating spicule or bone from the antrum.

Owing to lack of time and in two cases to the absence of the authors, the following papers were read by title only, but will appear in the published transactions of the association for the year:

(1) BONY CYST OF THE ANTRUM; REPORT OF A CASE, BY DR. CORNELIUS G. COAKLEY OF NEW YORK.
(2) REMOVAL OF NASO-PHARYNGEAL TUMOR; REPORT OF CASE, AND DESCRIPTION OF A NEW INSTRUMENT FOR THE OPERATION, BY DR. E. FLETCHER INGALS OF CHICAGO.
(3) A CASE OF GANGRENE OF THE TONSIL, BY DR. CHARLES W. RICHARDSON OF WASHINGTON.
(4) NASAL POLYPI. A STUDY OF 145 CASES, BY DR. J. PAYSON CLARK, OF BOSTON.
(5) CONGENITAL LARYNGEAL STRIDOR, BY DR. JAMES E. NEWCOMB, OF NEW YORK.
(6) A STUDY OF CERTAIN ACUTE INFLAMMATIONS AT THE BASE OF THE TONGUE, BY DR. ALEXANDER W. MACCOY OF PHILADELPHIA.
(7) MEDICAL TREATMENT OF ADENOIDS, BY DR. WILLIAM C. GLASGOW OF ST. LOUIS.

At the executive session of the association the following new members were elected:

To corresponding fellowship: A. Anodi, Budapesth; P. McBride, Edinburgh; Herbert Tilley, London.

To active fellowship: Thomas J. Harris, New York; Clement F. Theisen, Albany; Francis R. Packard, Philadelphia; W. Scott Renner, Buffalo; William Lincoln, Cleveland.

The following officers were elected for the ensuing year: President, J. H. Hartman, Philadelphia; vice-president, J. H. Lowman, Cleveland; second vice-president, W. P. Porcher, Charleston, S. C.; secretary and treasurer, James E. Newcomb, New York; librarian, J. H. Bryan, Washington; member of council, Jonathan Wright, Brooklyn.

The next meeting will be held at Atlantic City.

Recent Literature.

Syphilis in Dentistry. By L. BLAKE BALDWIN, M.D., Chicago Ill., Professor of Dermatology and Venereal Diseases, Post-Graduate Medical School, etc., etc., and EZRA READ LARNED, M.D., Chicago, Ill. Chicago: E. H. Colegrove. 1903.

This is a valuable book which sounds a note of warning and directs the attention of dentists to a danger which they have never sufficiently heeded, if they have not ignored it altogether. It calls attention to the frequency with which extra-genital infections occur. It gives directions for recognizing these, and calls attention to the differential diagnosis between syphilitic and non-infectious lesions of the mouth and adjacent parts. It cites a number of interesting cases and presents several excellent illustrations which should serve to arouse the vigilance of the dentist and enable him to detect this loathsome disease whenever its physical signs are present.

The Essentials of Histology, Descriptive and Practical. By E. A. SCHAFER, LL.D., F.R.S., Professor of Physiology in the University of Edinburgh; formerly Jodrell Professor of Physiology in University College, London. New (6th) edition, revised and enlarged. In one octavo volume of 426 pages, with 463 illustrations. Cloth, $3.00 net. Philadelphia and New York: Lea Brothers & Co.

Schäfer's excellent manual has been greatly improved in the present edition, which is far better printed than any of the five previous editions. The illustrations have greatly benefited by the better presswork, and the new figures which have been added are especially excellent. The paper used is thin and opaque, so that the volume remains thin, despite the increase of the number of pages to over 400. The text exhibits a careful revision, and is much improved, notably in the account of the central nervous system. The author's style is so clear, and he brings out so well the points which are important to medical students that the book has become, so to speak, a standard favorite. The chapter on the kidney is the only one which seems unsatisfactory — it needs to be worked over, and we think that figures of typical sections of the human kidney should be added. In the next edition we hope the author will include an account of the blood sinusoids, and of the development of lymphatics from veins. As a whole the present edition deserves a cordial welcome, and the volume may be recommended as a reference work which includes many facts not considered in most manuals of histology. C. S. M.

A System of Physiologic Therapeutics. Edited by SOLOMON SOLIS COHEN, A.M., M.D. Volume X, Pneumotherapy including Aërotherapy and Inhalation Methods and Therapy. By DR. PAUL LOUIS TISSIER. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

The tenth volume of this series on pneumotherapy has appeared in 479 pages, including a rather unusually complete index. We have from the first had words of commendation for this excellent series of volumes on rational therapeutics, and we see no reason to change our attitude in looking over this last volume. Certain changes have been made in the details of this volume, in giving, for example, more space to the history of the development of the subject under discussion and to the details of physiological experiments and postmortem studies. In part second in Inhalation Methods certain aspects of pharmacology are given considerable attention. This is perhaps the first departure from the strict intent of the series to devote itself wholly to physiological therapy, but is certainly justified by the needs of the subject under discussion. In connection with each of the methods discussed considerable attention is given to special therapeutics, a plan which possibly detracts from system but adds to practical usefulness. In general we would recommend this book as an adequate presentation of a subject little understood by the ordinary medical man.

The American Year-Book of Medicine and Surgery for 1903. A yearly Digest of Scientific Progress and Authoritative Opinions in all branches of Medicine and Surgery, drawn from journals, monographs and text-books of the leading American and foreign authors and investigators. Arranged, with critical editorial comments, by eminent American specialists, under the editorial charge of GEORGE M. GOULD, A.M., M.D. In two volumes. Volume I, including General Medicine. Octavo, 700 pages, fully illustrated; Volume II, General Surgery. Octavo, 670 pages, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

This now well known and excellent year book appears this year, as for the last two years, in two volumes instead of one. One of these volumes is devoted to surgery, the other to medicine, and it is of interest to note that in the opinion of the compilers these general subjects are of so nearly equal importance that the volume on medicine is but twenty pages longer than that on surgery. Through the death of Dr. Charles H. Burnett the departments of otology and laryngology have been united under the editorship of Dr. D. Braden Kyle, a change which the editor, Dr. Gould, regards as a proper logical and clinical combination. The object of these books, as implied in their title, is to epitomize the more important work of the year under proper subheadings. This continues to be done by men eminently fitted for the work, which is a guarantee that the essential points of progress are brought out. We could wish that a further personal estimate of progress might be permitted space in the volumes. It would undoubtedly be of advantage to readers could a general summary with critical comment be made at the end of each of the sections. The binding and general appearance of the books are, as heretofore, wholly satisfactory.

THE BOSTON

Medical and Surgical Journal

THURSDAY, AUGUST 6, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

INVESTIGATIONS ON THE ACTION OF CHLOROFORM.

ON July 10, 1901, a special committee was appointed by the British Medical Association to investigate chloroform in its therapeutic uses. The ultimate aim of the research was to determine the minimum dose of chloroform capable of producing adequate anesthesia without endangering life. The practical importance of such an investigation, in view of the reputed danger from the use of chloroform as an anesthetic, especially in consideration of the suspicion with which ether is apparently regarded in Continental countries, is self-evident. The uncertainty of dosage, the varying methods employed in administering the anesthetic and the occasional fatal outcome of its use, together render such an investigation as that inaugurated by the British Medical Association most timely. The first report of the committee was published in the *British Medical Journal* for July 12, 1902, and a second report appears in the issue of July 18, 1903, the latter undertaken by Dr. C. S. Sherrington and Miss Sowton. An excellent editorial summary of the work done also appears in this issue of the *British Medical Journal*.

The task set the committee was primarily to determine what proportion of chloroform entered the blood and became stored in the tissues, how much left the body during expiration, and whether or not any of the specialized tissues showed selective power in retaining the drug. The question of personal idiosyncrasy was also naturally considered. A further practical step in the research was to determine whether the ordinary methods of administrating chloroform were trustworthy and safe. The general conclusion reached regarding this latter point is that it is absolutely necessary to regulate the dosage of chloroform, and that an apparatus is eminently desirable which will on the one hand permit the administration of a definite dose capable of providing anesthesia and on the other not endanger life. The committee has furthermore reached the conclusion that safety depends upon dosage, by which is meant the proper percentage mixed with air. Concentration has been shown to be fatal, even in small amount, whereas it is maintained that a vapor below 2% is wholly safe, and that in most patients as low as 1% will maintain anesthesia. In view of these facts it is suggested that it would be of importance to learn what the common percentage of chloroform is as given by the ordinary more or less inexact methods.

Having established this fact, a further step was to determine with scientific accuracy what the physical effects of various percentages were. This is the essential problem discussed in this last paper of Professor Sherrington and Miss Sowton. They worked with the isolated mammalian heart and reached certain conclusions of much theoretical and practical importance. They found, for example, that heart muscle takes up chloroform from fluid circulating in the coronary vessels and that its lethal effects vary according to the fluid used. In diluted blood, for example, the chloroform gives less effect than in saline solution. With the increase of chloroform in the circulating fluid, more is taken up by the heart muscle until finally toxic effects are manifest. With weaker doses an equilibrium appears to be established between the chloroform-containing fluid and the heart muscle, so that finally no further effect upon the muscle manifests itself, in spite of the continuance of the flow of the chloroform fluid. This in a measure controverts the idea that chloroform has a cumulative effect upon the heart. It was furthermore shown by these experiments that the ventricle is paralyzed in its action before the auricle when toxic doses are used. These effects and others, to which we have not space to allude, bring out clearly the extreme importance of restricting the dosage of chloroform to relatively weak percentages, and show that the size of the dose circulating in fluid through the heart is the important element rather than the length of time during which it circulates.

The final results of this important and too long-delayed research group themselves about dosage and cumulation. It has been shown that chloroform is fatal in certain doses, the limit of which is regarded as abut 2%. Higher concentrations should be looked upon as potentially dangerous since their tendency is, other things being equal, to paralyze the heart muscle. The prolongation of the anesthesia with a dilution under 2% is not to be regarded as dangerous, although naturally individual susceptibility must be taken into account, and, as usual, arguments drawn from animals cannot be forthwith and without modification applied to man. The *British Medical Journal* expresses the hope that as the results of this and other similar investigations on the action of chloroform a method will be found whereby the strength of the anesthetic may be so absolutely regulated according to the requirements of the individual case that danger will be practically eliminated. It is urged that the danger of administering chloroform consists in giving an overdose, and that all precautions must be taken to provide that definite percentages alone are administered.

It is not our purpose here to take up the old controversy regarding the relative value of chloroform and ether as general anesthetics. The success attending the use of ether in this country, and its practical freedom from the dangerous effects which are admittedly present in the use of chloroform, continue to excite our wonder that the Continental countries have been so slow in adopting its general use. At the same time it must naturally be admitted that chloroform, if not always, is frequently a most desirable means of anesthesia, and that any researches which tend to the minimizing of danger in its use must be most heartily welcomed. The theoretical and practical importance of this work undertaken by the British committee must be very far-reaching in its effect.

MUNICIPAL HOSPITAL FOR TUBERCULOSIS.

IN 1901 the sum of $150,000 was appropriated in the General Loan bill of Boston providing for a hospital for consumptives. Under an ordinance passed by both branches of the city council an institution was to be established to be under the supervision of a board of trustees similar in general character to the Boston City Hospital. The provision was made that no patient treated in this proposed institution should be allowed to pay. On this ground the ordinance was vetoed by Mayor Hart, although he was in favor of the general proposition. Mayor Collins, on assuming office, declined to consider the matter, on the ground that the amount of money appropriated was too small for the establishment of such an institution. The matter was then allowed to remain quiescent, and it is only within two weeks that the question has again been revived by an order introduced in the Common Council amending the ordinance, whereby permission is given to the Board of Health to establish a city hospital for consumptives. This has been passed by the Common Council, and on Monday of this week was also passed by the Board of Aldermen without opposition. The matter is, therefore, now before the mayor for his approval or veto.

It has long been evident that the Boston Board of Health has been hampered in its fight against tuberculosis on account of the fact that there was no suitable hospital to which persons who were on account of their disease a menace to the community could be sent, excepting the special departments for tuberculosis at the Tewksbury Almshouse and at the Long Island Hospital. Owing to the somewhat unjust laws regarding declaration of pauperism before persons may be treated in these institutions, it is natural that a very great predjudice should have existed against entering either of them. This naturally has hampered the Board of Health in enforcing the somewhat rigid laws which have recently been enacted in accordance with the modern theories of the contagiousness of tuberculosis. It is apparent either that the stigma of pauperism should be removed from patients entering the state or city institutions, or else that other provision should be made for their proper care. In view of these facts, it is altogether desirable and, in fact, is rapidly becoming imperative that the city should provide for this class of persons. It is to be understood that the proposed institution is for the treatment of chronic cases, which are not necessarily past improvement, but which nevertheless cannot be admitted to the Rutland or to the Sharon Sanitarium. In the opinion of those who are qualified to judge of the matter it is felt that, although the amount of $150,000 is small to effect marked amelioration in the present conditions, nevertheless it should serve as a means of demonstrating the future possibilities of relief which the further prosecution of the work will bring to pass. Certainly a hospital of one hundred beds would greatly relieve the immediate necessities which exist in the city at the present time.

PREVENTION OF TUBERCULOSIS.

THE New York Charities Committee on the Prevention of Tuberculosis has just issued a series of interesting charts, prepared under the supervision of Dr. H. M. Biggs, with explanatory data, which show something of the conditions relative to the disease on Manhattan Island and of the work accomplished by the Health Department, with the co-operation of the medical profession and various organizations, during the last twelve years, by means of which the death-rate from tuberculosis has been materially reduced. The reduction from 1886 to 1902 is from thirty-eight deaths per thousand inhabitants to twenty-two, and from 1889, when the department first took active measures along the lines now followed, from thirty-three deaths per thousand to twenty-two. In the last decade there is an indicated decline of nine points in the death-rate for Manhattan, as against a decline of six points for the United States at large. The following comments by Dr. Biggs, who has had exceptional opportunities for observation, are worthy of note: "On the charts comparing the death-rate for New York and for the country at large, I have no hesitation in saying that if our efforts are kept up and advances made which are in the line of development of preventive medicine, the time will come when New York City will be relatively more free from consumption than the country as a whole. I can say this because consumption is a disease which may be controlled absolutely, and it only depends on the efficacy of the measures taken to control it. It is, of course, impossible to predict the rate of decrease, because that depends entirely upon what advances are made. So it is impossible also to say that at any indicated time, or ever, consumption as a disease will be stamped out entirely; but this may be said, that there is no more reason for consumption in the community than there is for smallpox. The advances for the past fifteen years, and since the Health Department began its campaign, have been marked by a rapid decrease in the death-rate. This has probably been more rapid than will be the decrease in the next fifteen years, because such measures have to become more and more effective to produce the same degree of result when the general condition is improving all the time. A reduction of forty per cent would bring the death-rate very low indeed, but whether this is accomplished in the next fifteen years, or the next quarter of a century, will depend entirely on the support that the public gives to the measures that are taken in fighting tuberculosis." It is stated that at the present time fully eighty-five per cent of all cases of consumption in New York are reported to the Board of Health, and that the inspectors of the board visit all tenement-house cases unless the attending physician requests that no visits be made. The department also has power to enforce the removal of patients to hospitals if required.

BISHOP BRENT'S WORK IN THE PHILIPPINES.

WE have on various occasions commented upon the active medical work which has been inaugurated in Manila through the energy of Bishop C. H. Brent, not long since sent as a missionary bishop by the Episcopal Church to the Philippines. Bishop Brent has apparently from the first recognized the absolute necessity of providing more adequate medical care for the ignorant and often superstitious natives with whom he has been called upon to deal. Largely through his efforts a general hospital for Manila is soon to open its doors for the treatment of patients. In other ways also he has shown his conviction that very much may be done toward the spiritual enlightenment of the natives by a preliminary care of their physical needs and diseases. In a private communication he dwells upon the very great desirability that missionaries in the Philippines should have a medical and surgical education, and expresses with regret his own deficiency in that direction. Speaking of certain natives at a distance from Manila, and work which he has undertaken among them, he says: "C. feels as I do about the importance of medical work, and he is fairly well equipped to begin it. Later on a nurse and a doctor are going up. I asked Mr. P. to give me a ton of Ivory soap for that region, — cleanliness is the hither side of Godliness, I think! — and he did so without a moment's hesitation."

The dispensary in Manila has up to this time been a success. About 250 patients of the poorest classes are under treatment, and other dispensaries are on the point of being opened. In general it is evident, from Bishop Brent's letter as well as from other news that has reached us, that he and the church which he represents is doing an excellent work in attacking in so rational a way the difficult problems which are

presented. It is fortunate for all concerned that so far seeing a man has been chosen to pioneer this difficult work. We cannot doubt, if the material wants of the natives with whom he is brought into contact are provided for as well as modern medical science permits, that the deeper problems which lie behind physical conditions will be far easier of solution.

MEDICAL NOTES.

IN HONOR OF THE LATE MAJOR WALTER REED, M.D., U.S.A. — A meeting will be held at the Hotel Louisburg in Bar Harbor, Me., on the morning of Saturday, Aug. 15, 1903, at eleven o'clock, to confer with respect to a memorial in honor of the late Major Walter Reed, M.D., U.S.A., to whom the world is indebted for most important services in the investigation and the suppression of yellow fever. Several committees in different parts of the country have already been appointed, and the object of this conference is to secure unanimity of purpose and concerted action. Addresses may be expected from gentlemen who are well acquainted with all the facts.

DEATH OF PROF. EDMOND NOCARD. — It is reported that Prof. Edmond Nocard, well known as a bacteriologist and former associate of Pasteur, died in Paris August 2.

A NEW JOURNAL ON CANCER INVESTIGATION. — A new journal under the auspices of the German Cancer Investigation Committee is about to be published under the title *Zeitschrift für Krebsforchung*, to be devoted to the publication of articles on cancer and abstracts on the subject appearing in various languages. It is to be published by Gustav Fischer of Jena, under the editorship of Professor Hansemann of Berlin and Meyer of Jena.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Aug. 5, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 34, scarlatina 15, typhoid fever 29, measles 22, smallpox 0.

VANDERBILT WARD OF THE NEWPORT HOSPITAL. — On Aug. 1 the trustees of the Newport Hospital formally received from Mrs. Vanderbilt a ward erected on the hospital grounds as a memorial to her husband, the late Cornelius Vanderbilt. In addition to the gift of the building, it is said that a generous endowment for the conduct of the new ward has likewise been provided. The ward itself, which is said to have cost $250,000, is naturally equipped in the most modern possible fashion, and is to be used for the needy poor and for those who are able to pay but a nominal sum for treatment. The gifts of several members of the Vanderbilt family to this hospital are said to amount to upwards of $500,000.

EYESIGHT OF RAILROAD EMPLOYEES. — Examination of the eyesight of employees of the Boston & Albany Railroad has recently been undertaken, with the reported result that many of the older employees of the road have been superseded. Unjust as the rigid enforcement of this test may seem, it is nevertheless imperative, as shown by certain recent accidents, that employees whose duty it is to recognize signals should have absolutely no defects of vision. It is said that hereafter a semi-annual examination will be instituted.

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH. — By the invitation of the Boston Health Department the Massachusetts Association of Boards of Health was entertained at Gallops Island, Boston Harbor, July 30, the attendance being about one hundred and fifty. Mr. William Lyman Underwood of the Massachusetts Institute of Technology discussed the question of mosquitoes and methods of extermination. Mr. B. R. Ricards of the Boston Board of Health laboratory epitomized certain experiments on the comparative values of disinfectants.

APPOINTMENT OF DR. THEODORE CHAMBERLAIN. — At a recent meeting of the executive council Governor Bates of Massachusetts appointed Dr. Theodore Chamberlain of Concord medical examiner for the sixth Middlesex district. Dr. Chamberlain was a graduate of Harvard College and of the medical department of Columbia University. His experience since his graduation in 1895 justifies his appointment to this post of responsibility.

NEW YORK.

MORTALITY STATISTICS. — The Bureau of Records of the Health Department has just issued its report for the first quarter of 1903. The mortality in the city during that time represented an annual death-rate of 19.74 against a death-rate of 20.52 in the corresponding quarter

of last year. The corrected death-rates, excluding non-residents and infants under one week old, were respectively 18.73 and 19.63. Comparing the mortality with the average number of deaths and the death-rates of the corresponding quarters for the preceding five years, it is found that the number of deaths for the first quarter of 1903 was 18,156, which, on an estimated population of 3,732,903, gave a death-rate of 19.74 per thousand, as against an average number of deaths for the preceding five years of 17,773, which, on an estimated population of 3,448,567, gave a death-rate of 20.92 per thousand, a lowering of 1.18 points. The death-rates of the following diseases are compared because of their prominence from a preventive standpoint and as influential factors in the production of mortality rates: Average death-rate, 1898–1902, diphtheria and croup, 0.72; measles, 0.28; scarlet fever, 0.32; typhoid fever, 0.11; pulmonary tuberculosis, 2.52; influenza, 0.38; pneumonia, 3.92; cancer, 0.64; Bright's disease, 1.69. Death-rate, 1903, diphtheria and croup, 0.65; measles, 0.13; scarlet fever, 0.23; typhoid fever, 0.13; pulmonary tuberculosis, 2.42; influenza, 0.33; pneumonia, 3.63; cancer, 0.75; Bright's disease, 1.77. All the infectious diseases, especially measles, thus show a decreased death-rate, with the exception of typhoid fever, which shows a slight increase. On the other hand, cancer and Bright's disease show a considerably increased rate, in line with the views of competent observers as to the increase of these two diseases within comparatively recent years. There were 2,013 more births and 725 more marriages reported than during the corresponding quarter of last year.

A DAILY MEDICAL JOURNAL. — The Medical Publishing Company of America, an organization composed exclusively of physicians, has acquired from the Medical Critic Publishing Company the monthly journal *The Medical Critic*. Dr. Albert Warren Ferris has been appointed editor in the place of Dr. Frederic R. Sturgis, who recently resigned, and the staff of associate editors will remain the same as before. Dr. M. W. Curran also continues as managing editor. Encouraged by the financial success of the monthly, which has secured a large amount of advertising, the new company announces that, beginning with the first of October, it will publish a daily, to be known as *The Daily Medical Journal*, "which will unite energy and enterprise with a conservative regard for the ethics which should govern our profession, as well as the absolute independence which has characterized the policy of *The Medical Critic*." The proposed daily will consist of six pages, each 12 x 15 inches, and made up of four columns, and it is stated that the necessary equipment to print one hundred thousand copies each day has already been purchased.

DEATHS FROM INFLUENZA. — The last monthly bulletin of the State Board of Health, reviewing the mortality of the last six months, devotes considerable attention to deaths from influenza as affected by age. The figures show that more deaths are ascribed to it in the first year of life than in the next twenty. With the exception of the susceptible age of infancy, however, the first decade, and, in fact, the first twenty years, seem to be almost immune to the effects of the disease, and the middle period of life, to the age of forty-five or fifty, is resistant to it, so far as the reported mortality is an indication. Only one fourth of the deaths occurred prior to the age of fifty, after which there is a marked increase in each decade, the greatest number falling between the ages of seventy and eighty. The months of December, January, February and March, during which influenza is prevalent, show a much larger mortality at seventy years of age and over than the remainder of the year. Except during the first year of life, there are considerably fewer deaths from the disease among males than females; this is the case in every decade, and the discrepancy is especially marked in old age.

NOTES FROM THE PHILIPPINES.

RELAXATION OF QUARANTINE DESIRED. — The natives of the Mariquina valley, through which flows the river from which the Manila water supply is drawn, have petitioned the health authorities for a relaxation of the quarantine that is being maintained over the river. It is urged by them that as there is no longer any cholera in the valley this restriction can be removed without danger. The Mariquina watershed was quarantined as soon as the first cases of cholera appeared here, and was maintained for some months by military guards and mounted patrols. When the epidemic abated the quarantine was relaxed; but a sharp recrudescence of the disease caused a second and even more stringent quarantine to be imposed, which is still maintained in all its rigidity. A zone has been established on both sides of the river from which the natives are

kept away by mounted patrols. This careful quarantine has been of the utmost value to the sanitation of Manila, since, although cholera foci are scattered all through the islands, only a few sporadic cases of the disease have occurred in Manila for the past four months, and these have occurred in new arrivals from the provinces or were apparently due to the use of food introduced from infected points. In view of the continued danger of cholera, particularly during the early part of the approaching rainy season, there is no chance that the Mariquina quarantine will be abandoned or relaxed to any great extent.

Report of Board of Health. — The report of the Board of Health for the month of January, just issued, gives the average annual death-rate for the city of Manila, per thousand, for the month, as 23.46 for all nationalities. The death-rate for the Filipinos was 29.15, foreigners, 9.00; Chinese, 7.18; Americans, 6.05. There were 635 deaths, of which 319 were under one year of age. The birth-rate, as based on reports received by the Board of Health, was 5.61, but it is admitted that the returns in this respect were incomplete. Of the total number of deaths, 328 occurred with medical attendance and 307 without medical attendance. There were four deaths from cholera and but one from plague during the month. The number of deaths from cholera reported from the provinces during the same period was 1,180. These deaths occurred in 1,662 cases, giving a mortality of 70.99%. There were 77 towns reporting cholera during the month. In Manila there were 13 deaths from malaria, 27 from beriberi, 61 from pulmonary tuberculosis and 236 from eclampsia and convulsions of children. The annual death-rate for the month was lower than for January, 1902, with a rate of 30.16, and lower than that January, 1901, in which the rate was 36.22. Excepting during the cholera epidemic an almost steady decrease of the city death-rate has been the result of sanitary control by the Americans, and further improvements may be expected as the situation is bettered by the present improved sanitary organization and facilities. A total of 179,992 sanitary inspections of houses was made during the month; 17,078 houses were cleaned, repaired or destroyed under the orders of the sanitary inspectors, and 16,067 houses were disinfected; 1,382 cesspools were cleaned, 12,892 yards cleaned and 72 yards repaved. A total of 15,340 vaccinations were performed during the month — there were no cases of smallpox. There were 7,143 sanitary inspections of boats and watercraft in the port of Manila. The leper census to date, for the entire islands, shows 3,307 cases of this disease known to the authorities.

Proposed New General Hospital. — The proposed new general hospital will probably be located in the district of Malate, on a piece of property owned by the city. The committee in charge has made a formal request for that site. The ground is comparatively high and of sufficient area to meet the needs of the hospital for many years. It will also be very close to the government laboratories, which will be called upon to make the necessary examinations and analyses. The tract is a valuable one, but the city has no immediate need for it. If the request is granted, it will remove the necessity of starting a subscription for the purchase of a site. The resolution of the government to erect the hospital buildings and provide for their maintenance pronounced in favor of a site in the district of Santa Mesa, but expressly stated that the decision in that respect was not final. The Malate site is closer to the center of the city and quite as well adapted otherwise for hospital purposes as that at Santa Mesa.

Miscellany.

INFANT MORTALITY IN BOMBAY.

In a paper read before the Bombay Medical and Physical Society upon Infant Mortality in Bombay, Dr. D. R. Bardi pointed out that in 1899 the infant mortality was 593 per 1,000 births, and 867.67 per 1,000 of population amongst children under one year. Comparisons show that matters are growing worse rather than improving. Twenty-two "tables" are given, and from an examination of those bearing upon the causes of death it is seen that debility is most potent under seven months, whilst respiratory and nervous diseases kill many more before two years of age. This is largely due to overcrowding, bad sanitation, poverty, ignorance and superstition. The remedies consist in the enforcement of sanitary measures, education in hygienic principles and the minimizing the ill-effects of the condition of the poor. The excellent results of the Vaccination Acts show the advantages of compulsory sanitary laws. Impure milk supply is another serious menace to infant life, and suggestions are made that dispensaries should be attached and nurseries built where infants could be left in charge of nurses while their mothers were at work. By authoritative measures much of the infant mortality in Bombay could be prevented and the causes of its high percentage to a large extent removed. — *British Medical Journal.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JULY 25, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Scarlet fever.

Deaths reported, 3,302; under five years of age, 1,438; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,262, acute lung diseases 213, consumption 332, scarlet fever 26, whooping cough 31, cerebrospinal meningitis 10, smallpox 18, erysipelas 4, measles 29, typhoid fever 52, diarrheal diseases 689, diphtheria and croup 65.

From whooping cough, New York 3, Chicago 7, Philadelphia 12, Pittsburg 5, Boston 2, Lowell 1, Lawrence 1. From erysipelas, New York 1, Chicago 3. From smallpox, Chicago 1, Philadelphia 11, Pittsburg 6.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending July 11, the death-rate was 13.7. Deaths reported, 3,969; acute diseases of the respiratory organs (London) 127, whooping cough 90, diphtheria 47, measles 89, smallpox 5, scarlet fever 53.

The death-rate ranged from 5.3 in Smethwick to 26.0 in Wigan; London 13.3, West Ham 12.9, Brighton 8.3, Portsmouth 13.9, Southampton 9.9, Plymouth 9.3, Bristol 10.9, Birmingham 14.6, Leicester 13.3, Nottingham 13.8, Bolton 17.7, Manchester 15.4, Salford 14.3, Bradford 12.7, Leeds 13.3, Hull 14.6, Newcastle-on-Tyne 18.3, Cardiff 11.8, Rhondda 17.0, Liverpool 17.0, Hornsey 7.3, Merthyr Tydfil 19.6.

METEOROLOGICAL RECORD.

For the week ending July 25, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING AUG. 1, 1903.

M. H. SIMONS, medical director. Commissioned medical director from June 9, 1903.

DRS. S. L. SCOTT, T. N. PEASE and F. G. ABEKEN appointed assistant surgeons from July 10, 1903.

E. MAY, hospital steward. Appointed pharmacist from March 28, 1903.

T. N. PHILLIPS, hospital steward. Appointed pharmacist from June 8, 1903.

E. M. BLACKWELL and G. F. FREEMAN, passed assistant surgeons. Commissioned as such from June 7, 1903.

C. E. RYDER, assistant surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

RECENT DEATHS.

GORTON HERBERT RACE, M.D., M.M.S.S., died in Great Barrington, July 22, 1903, aged fifty years.

LAWRENCE STEWART EDWARDS, M.D., of Patchogue, Long Island, N. Y., died on July 25, at the age of forty-eight years.

ALBERT JEREMIAH SCHUREMAN, M.D., of Newark, N. J., who was a descendant of a signer of the Declaration of Independence, died on July 29, at the age of seventy-four. One of his brothers, Dr. Charles A. Schureman, is a practising physician in Newark.

BOOKS AND PAMPHLETS RECEIVED.

A Pharmacological Study of an Aseptic Preparation of Ergot devised for Hypodermic and Internal Administration. By E. M. Houghton, Ph.C., M.D. Detroit, Mich. Reprint, 1903.

Three hundred and sixty-two Vaginal Hysterectomies for Cancer, with 28 absolute cures; and Collection of 263 other cures by 76 operators in the Mississippi valley. By Emory Lamphear, M.D., LL.D., of St. Louis, Mo. Reprint, 1902.

Sight and Hearing in Childhood. By Robert Brudenell Carter, F.R.C.S., and Arthur H. Cheatle, F.R.C.S. Illustrated London: The Scientific Press, Limited.

Plain Hints for Busy Mothers. By Marianna Wheeler. Illustrated. New York: E. B. Treat & Co. 1903.

A Manual of Obstetrics. By A. F. A. King, A.M., M.D. Ninth edition. Revised and Enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

Diseases and Injuries of the Eye with Their Medical and Surgical Treatment. By George Lawson, F.R.C.S.(Eng.). Sixth Edition. Revised and in great measure re-written by Arnold Lawson, F.R.C.S. (Eng.). Illustrated. London: Smith, Elder & Co. 1903.

An Experimental Investigation of Trypanosoma Lewisi. By Edward Francis, M.D. Bulletin No. 11. U. S. Public Health and Marine Hospital Service. February, 1903.

THE PRESENT STATUS OF THE SURGERY OF THE PROSTATE GLAND.[1]

BY PAUL THORNDIKE, M.D., BOSTON.

THE reader has been asked to give a short *résumé* of the present condition of prostatic surgery. It becomes evident at once that to do this in the fifteen minutes' time allotted for the purpose makes a detailed account of technical procedures quite impossible, and little more can be attempted than to mention briefly the various steps which have brought prostatic surgery where it is to-day, and to consider with equal brevity the class of cases best adapted to each of the operative procedures which are in use at the present time. If this paper serves to help the practitioner of medicine to formulate and arrange his ideas as to the treatment of cases of obstructive enlargement of the prostate which are so common in every physician's practice, its object will have been attained.

Bottini performed his first cautery operation over thirty years ago and continued the use of his instrument up to the time of his very recent death, but the operation never gained an extensive repute until within the last few years. Belfield of Chicago performed the first prostatectomy in 1885, but it was not until the publication of a series of cases of prostatectomy, by McGill of Leeds in 1888, and the communication of Mr. McGill and his colleagues of the Leeds Infirmary, at the meeting of the British Medical Association in 1889, that the surgical world realized the practicability of a radical operation for the removal of obstructing prostatic masses.

Even during the last fifteen years hypertrophy of the prostate gland has been a condition to palliate and not to cure in the hands of most surgeons, and the men who have added radical operations upon the prostate to their list of routine procedures have been few indeed. How is all this changed! Almost every surgeon has done his few prostatectomies, and has his own ideas regarding the Bottini operation, even if he has not had actual experience in the performance of it. The surgical literature of the last two years amply demonstrates the fact that the surgery of the prostate is one of the burning topics of the moment and shows that the surgeon who contents himself with guiding all the patients who come to him for relief from this obstruction through years of more or less painful and dangerous catheter life, without offering them the relief which a prostatectomy or a galvano-cautery operation has to offer, is often indeed remiss in his duty.

In the earlier prostatectomies the organ was approached through a suprapubic incision into the bladder, and its removal was attempted piecemeal by instruments made for the purpose. The operation was a prolonged and bloody one, and no surgeon acquired large experience in its performance. Its mortality was something like 15%, and it was looked upon with enough dread by the profession at large to lead them to resort to a variety of other procedures of a less severe kind, all aiming at palliation without attempting the actual removal of the obstructing portions of the gland. Supra-pubic drainage, both temporary and permanent, incisions into and removals of portions of the gland through the urethra or through suprapubic or perineal incisions, castration, ligation of the vasa deferentia without castration, the galvano-cautery operation of Bottini and its modifications as instituted by Young of Baltimore and Chetwood of New York (the latter of whom performs the cauterization through a perineal incision with an instrument devised by himself), all will serve as examples of such procedures. Many of these palliative operations were so unsuccessful and others were so uncertain in their benefits that when it was realized that obstructing prostatic masses can be quickly and easily enucleated by the finger through a suprapubic incision, prostatectomy began to assume a real place in technical surgery, and a good many men acquired a considerable experience and skill with this suprapubic enucleation. In 1895 Nicoll of Glasgow, and in 1896 Alexander of New York, with a slightly different technique, demonstrated series of cases to show what Zuckerkandl in Vienna and Watson of Boston (1888) had pointed out as possible years before—that the prostate could be approached through a perineal incision. And as you all know, the perineal operation has become of late the one of choice in the minds of many surgeons. This fact has led to a very rapid improvement in the technique of the operation, an improvement which has been especially noticeable during the last year or two. Nicoll's perineal operation approached the prostate by a careful dissection between the urethra and rectum and opened the prostatic capsule from behind, thus making the operation a long and technically a difficult one. Alexander, while approaching the gland through a median perineal incision which opens the urethra but gives a quick and easy access to the organ, felt obliged to make a preliminary suprapubic cut into the bladder in order to push down the prostate from above into the perineal wound with a finger in the bladder. This involved two cuts instead of one, and the serious complication of opening the bladder, with the risks of suprapubic asepsis attendant upon that procedure. Guiteras endeavored to avoid this complication by making the suprapubic incision only into the prevesical space (and not into the bladder cavity), pushing down the prostate from there by introducing a finger between the bladder and symphysis pubis. At this time it became very evident that the future improvement in the technique of the perineal operation depended upon the omission of the suprapubic cut, and the accomplishment of the entire operation through the perineal incision. At the same time the difficulty of reaching the prostate

[1] Read before The Massachusetts Medical Society, June 9, 1903.

through a perineal wound without making large and extensive dissections became so apparent that various instruments were constructed to serve as tractors to pull down the prostate into the perineal wound, where it would be more easily accessible. Guiteras of New York devised an instrument of this kind, shaped a good deal like a sponge forceps with fenestrated blades, and designed to grasp the prostatic tissue through an opening in the prostatic capsule made for the purpose of enucleation through it. Syms of New York made an ingenious tractor of a different sort, which consisted of a rubber bulb on the end of a strong rubber tube. This bulb was passed into the bladder through the perineal wound and then inflated with air so that traction upon it served to bring the prostate down within easy reach. Ferguson of Chicago has devised retractors which he inserts into an incision into the posterior aspect of the prostatic capsule through a perineal wound, and so drags the prostate down within reach by traction upon its capsule and without passing any traction instrument into the bladder. Murphy of Chicago has devised similar tractors shaped like rakes; and finally Young of Baltimore has constructed what is perhaps the best of all these tractors, in the shape of a steel instrument with two fenestrated blades which can be readily inserted into the bladder and then opened out into a figure of eight behind the prostate. He thinks this instrument gives him firmer and better traction than he can get in any other way.

The last year or two, then, has demonstrated clearly the fact that the prostate can be readily approached through a perineal incision, and can be as readily brought within the reach of the surgeon without the necessity of a suprapubic incision. And now comes from Young of Baltimore the last development of the technique of the perineal operation. This consists in bringing the prostate well into reach and sight by traction made with his tractor just mentioned, and then removing the bulk of the obstructing glandular tissue through two lateral incisions in the prostatic capsule, leaving an intact urethra and also a narrow median zone of tissue just above the urethra, and containing the ducts from the seminal vesicles. So this operation aims to be a conservative procedure which leaves the generative powers of the individual unimpaired. This operation was described by Young at the last meeting of the American Association of Genito-Urinary Surgeons, held at Washington last May, but his paper has not yet been published. He has operated upon several cases recently and believes that he has succeeded in saving the generative apparatus unimpaired in a number of these cases.

During these years of the development of prostatectomy there have been always so many cases demanding relief which the catheter could not give, and yet cases which were obviously too infirm to be fit subjects for any severe surgical procedure such as is prostatectomy, that the need of other less severe and perhaps also less radical measures has been almost as great as ever. This need was accentuated by the fact that castration failed to give the permanent relief to such cases which was claimed and expected from it, and also proved, as clearly shown by Cabot in his report to the American Surgical Association, to be almost as dangerous as the more radical operations attacking the prostate itself. These conditions led many surgeons to turn back to the Bottini operation, which now for the first time is having a widespread trial. It is proving so satisfactory as a palliative operation, and its attendant risks are so much less than those which prostatectomy offers, that when it became certain that this operation can be performed when necessary without the aid of a general anesthetic, it was small wonder that it acquired so many adherents. The operation consists, as you know, in burning grooves through the obstructing portions of the prostate by means of a galvanocautery constructed for the purpose. It has always been claimed by the believers in prostatectomy that the Bottini operation is too uncertain in its results, and that it was often performed in the dark and for conditions of which too little accurate information could be obtained to be safe for general use; that if, on the one hand, the cauterizing blade be too superficially used, the results are bad, while if, on the other hand, they are made deeper, there is great danger of burning through into the periprostatic tissues and rectum. The reader has always shared these beliefs, and has never until recently employed this procedure; but when Young of Baltimore obviated this uncertainty of operation to a large extent by modifying the instrument in such a way as to provide different-sized blades for different-sized prostates, the accuracy of the operation was greatly increased; and now the reader believes firmly that with the knowledge which can be obtained by examination, and measurements with urethral instruments, by palpation (suprapubic and rectal) and by the cystoscope, which, when its use is feasible, will always give a fair idea of the conditions at the bladder outlet, the Bottini operation, as modified by Young's instrument, is sufficiently accurate to be safe in the hands of those familiar with its use; that it is applicable to perhaps a larger class of cases than any other single operative procedure; and that it can be performed without the use of an anesthetic other than cocaine should the necessities of the case require it. [Young's instrument shown.] The reader's own cases are too few in number to be worthy of tabulation, but they have encouraged him in his belief in the operation, and it is his hope to report before long a series of such cases to this society.

Now let us consider very briefly the class of cases in which these different procedures, both palliative and operative, are to be advocated:

Catheter. — The systematic use of the catheter has always been the chief means of palliating cases of prostatic obstruction. There are as

many, or more, cases to-day as ever when such palliation is possible and is to be advocated. Many of these go on throughout their lives in comparative comfort, and the danger from such a catheter life comes not during its proper continuance but through the hopeful efforts to continue it after its proper sphere of usefulness is past. Just at the moment when this becomes true, when, either through a lack of intelligence or a lack of proper surroundings on the part of the patient, or by reason of mechanical difficulties which prevent the easy and systematic use of the instrument such a catheter life becomes no longer easily feasible, then is the time for operative interference. The reader has operated in a few instances upon patients without advocating a catheter life at all, because in these individual cases, even though relief was sought early in the development of symptoms, the difficulties in the way of a proper catheter life were so manifest and so apparently insurmountable.

Prostatectomy. — A year ago the reader stated at a meeting in this hall that prostatectomy was *always* the choice for all cases which could no longer be palliated, and which were fair subjects for operation. This statement holds good to-day, and is based upon the fact that this operation is the only one which offers a cure for the condition with any considerable degree of certainty. It is, however, by no means proper to offer prostatectomy to all patients who have passed the stage of possible palliation, so long as other less dangerous expedients are at our command. Prostatectomy is an operation of considerable severity, and, when performed upon men past the prime of life, will always be attended with danger to life, no matter what improvements in its technique have taken or still may take place. Therefore, although its results are surest, it is adapted only to cases which are fair surgical risks, that is, to patients with fair heart and arteries, fair kidneys and a bladder which can be made clean and kept so. These conditions are not often present in patients over sixty to sixty-five years of age.

As to which operation shall be performed in cases where a prostatectomy has been decided upon this may be said: In spite of the great technical improvements which have lately been made in the perineal operation, improvements which have made the operation easier and more accurate of performance, and correspondingly less severe upon the patient, there is still a place for the suprapubic operation. This procedure offers and always will offer, as its great advantage, a visual inspection of the parts about to be attacked, which cannot be obtained in any other way. The cases especially adapted to its use are those of great enlargement, which involve the removal of enormous masses of glandular tissue. Such masses are always within easy reach of the enucleating finger, and their removal drops the bladder outlet, so that good drainage can usually be obtained through a catheter tied into the bladder through the urethra, and a perineal incision for drainage can usually be dispensed with. The disadvantages of the operation are a slightly longer convalescence, the possibility of sepsis in the suprapubic and prevesical tissues, and occasionally a tendency to hernial protrusion through the suprapubic scar. Up to the present time it has always proved a shorter, less severe and less dangerous operation in the reader's hands than the perineal operation; but the constantly improving technique of the latter and its ever-increasing ease and accuracy of performance will probably change all that. The perineal operation should probably be done in most cases when a good idea of the existing conditions to be attacked can be had prior to operation, and especially when a successful use of the cystoscope has rendered the intravesical conditions a known quantity. Now that the perineal route is developing conservative possibilities, and also is making the operation less traumatic and more accurate in character, it will become the operation of choice for most cases in the hands of the average surgeon.

The Bottini Operation stands proven beyond dispute a less dangerous procedure than prostatectomy, and as it can always be performed without a general anesthetic, and as it has a very short period of convalescence, the reasons for this fact can be readily understood. Its results, though not so certain as those of prostatectomy, are sufficiently good to gain for it a constantly increasing confidence, and the reader believes that this procedure should be offered to all cases which can no longer be made comfortable by palliative means and which are too infirm to make the risks of prostatectomy justifiable. Such cases will be found to compromise a very large percentage of all prostatics who present themselves to the surgeon for relief, and they are probably greater in number than any other one class of cases. The instrument as modified by Young unquestionably increases the accuracy of the cauterization and is, in the reader's belief, the best one to use.

Résumé. — To conclude, then, we may say:

(1) That no prostatic should be allowed to suffer for lack of proper treatment.

(2) That there is still a place for the catheter in such treatment, and that many patients can be made comfortable and can be kept so by its systematic and proper use.

(3) That all those patients who cannot be kept comfortable by palliative means are fit subjects for some operation.

(4) That the time for such an operation is just as soon as the inadequacy of palliative treatment is demonstrated.

(5) That the operation of choice is always prostatectomy, but that this operation can be properly offered to those patients only whose general conditions make them fair surgical risks, and that such is rarely the case after sixty to sixty-five years of age.

(6) That to all other patients the Bottini operation can be fairly offered as one attended

with little risk to life, a short convalescence, and a good prospect of such a degree of improvement as will at least do away with any further necessity for the systematic use of the catheter.

DISCUSSION.

DR. F. S. WATSON of Boston: I can add very little, I think, if anything, to what Dr. Thorndike has said. I want to join most heartily in commendation of Dr. Thorndike's paper. It seems to me that it very fully covers the ground and is admirably well balanced, and weighs the value of different proceedings in very just light. Practically all that I can do is to emphasize some few points already spoken of. The most essential point is that of the selection of the patients for whom the prostatic operations are desirable and of applying the method best suited to each individual case. There is no hard-and-fast line to be drawn in this respect according to the patient's age. The question turns upon the condition of the kidneys, and in this respect some men of seventy-five are quite as young as others of fifty-five.

We are better able to estimate the condition of the renal function, owing to the introduction of some of the recent methods, such as cryoscopy and the phloridzin test, etc., than we were formerly. But even without their aid, the renal capability of sustaining the shock of such operations as are the radical ones upon the prostate was sufficiently well shown by the usual methods of urinary analysis, and especially by one of its features which is peculiarly significant in these particular cases, — I mean the specific gravity of the urine. If this is found to be constantly low — 1012 or so — radical measures upon the prostate are fairly sure to be followed by serious or fatal consequences. The large majority of these patients die after operations of that sort from renal insufficiency, sepsis and other conditions playing but a relatively unimportant rôle in this respect.

But even in the absence of such danger signals all precautions should be taken against the occurrence of these fatal or alarming states in connection with operative procedures, and something may be done to avert them.

There is little that can be done with respect to guarding against the dangers arising from renal insufficiency. A suggestion made by Dr. MacGowan of California seems well worth following. He says that his dread of renal insufficiency in connection with operations upon the urinary organs has been greatly lessened owing to the employment of abundant subcutaneous injection of saline solution, which he employs as a routine measure at the beginning of every such operation, and which he credits with the power to avert subsequent failure of the renal function. Other than this and the usual precautions, such as guarding the patient from exposure to cold, etc., there is little to be done to ward off the danger from the defective renal action.

The risk from sepsis is very much less than from the other element just referred to, and more may be done to minimize it.

The most important thing to be done in this connection is, of course, to reduce — to cure is rarely possible — the cystitis if present beforehand, and to keep the bladder and operative field clean subsequently. The agents which I have found most useful for the former object have been urotropin, and for local application solutions of methylene blue and argyrol as bladder irrigations.

The most essential point in connection with these prostatic operations is the proper selection of the time at which to perform them. The longer my experience of these cases the more do I incline toward early operation, and the greater my disinclination to postpone surgical intervention until the use of the catheter has become inadequate.

When the latter point has been reached, the patient is already in a condition unfavorable for operation, and it will be performed in the face of dangers which, had it been done prior to this time, would not have been incurred, or at any rate, when they would have been very much less. In fact, the risk attending the performance of Bottini's operation in the early stages of this disease is very little indeed, and one which I am confident I shall incline to advise patients to assume more frequently, and at an earlier stage of the malady in the future, than has been my custom in the past.

My position as to the choice of methods is practically the same as expressed by Dr. Thorndike.

The performance of the perineal enucleation of the gland is, in cases in which it is appropriate, usually very easy. The essential factors in the rea ess with which it is done are fixation of the gland and the bringing of it as far down as possible on to the perineum. These may be secured by downward pressure from above the symphysis by the hand of an assistant upon the empty bladder, and by drawing it in the same direction by the tips of two fingers resting upon its upper border in the rectum, or probably better by means of such an instrument as that of Dr. Young, which Dr. Thorndike has just shown. I have not used the latter, and am therefore unable to speak more positively of it.

It is remarkable how easy the perineal operation may be in some cases — in one case I removed the whole gland in four minutes — and how difficult in others.

The choice of methods seems to me to be easily divided. In cases in which the cystoscope has shown it to be appropriate and adequate, the Bottini operation, though my personal experience with it is limited, is, upon the evidence in our possession, that of choice. In other cases the best plan to follow is, I believe, as I have frequently stated before, to open the perineal urethra by the usual incision, explore the condition of the gland with the finger, and then to remove it or its obstructing portions through the perineal incision when that is feasible, and

when it is not to proceed at once to the suprapubic operation.

One word with regard to the use of the cystoscope in these cases. It has one undoubted and great value, which is that it is capable of determining beforehand, as a rule, whether the case is appropriate for a Bottini operation or not, although it is possible to be misled even in this respect because of the inability to gauge the extent of the parts of the gland, and the degree of obstruction for which they may be responsible, which are not visible from within the bladder.

PRELIMINARY REPORT OF FIVE CASES OF RENAL DECAPSULATION.[1]

BY J. BAPST BLAKE, M.D., BOSTON,

Second Assistant Visiting Surgeon, Boston City Hospital.

THE following cases have been operated during the past nine months on the First Service of the Boston City Hospital. Three of them are reported through the courtesy of Drs. H. L. Burrell and J. C. Munro.

It has seemed advisable to record the progress in these five patients at this time, reserving a final and more complete statement for a period of about two years after operation. What might be called the immediate results and sequelæ are available now. The ultimate results, however, cannot yet be fully prognosticated.

Two of the five are, for the practical purposes of business and occupation, well. Two have died, at intervals of four days and six months after the operation. One is not relieved.

All of the cases were operated by two surgeons simultaneously, one decapsulating the right, the other the left kidney. The assistants have usually stood next the operator and not opposite him; with previous planning and a little practice, the members of this double team need not necessarily interfere materially with one another. The time of the double operation is thus reduced by nearly one half, and it does not appear that the patient is subjected to a noticeably increased amount of shock.

The patient has been placed prone, face downward, the head projecting beyond the end of the table, the shoulders protected (and slightly raised) by sheets, the neck being, of course, absolutely shielded from pressure. This seems to be best accomplished by having the etherizer support the head, placing a hand under the forehead. If large pads, thick sand bags or the wide rubber bag be used, care must be taken that the action of the diaphragm be not interfered with. If the bags are placed high in the epigastrium this result followed in several instances, and was made evident by cyanosis and even threatened collapse; these symptoms began to disappear almost immediately after the removal of the bags. If, on the other hand, the bags be placed too low, the angle between pelvis and thorax is not so well opened, and the kidneys may actually be displaced upwards. In a fat and edematous person, this may complicate the operation distinctly

The technique of the operation is simple and sufficiently well known to render a detailed description unnecessary. We have endeavored to preserve the lumbar nerves; arteries have been secured before opening the retro-peritoneal space. Occasionally one of the larger branches of a lumbar artery, cut and retracting into the muscle fibers, has caused an annoying hemorrhage. In thin patients it was sometimes possible to complete the operation without tying an artery. In fat and edematous patients the depth of the incision was surprising; and in such patients it was sometimes thought advisable to mark the outer edge of the erector spinæ muscle before operation, for it is at times difficult, in the presence of much edema, to accurately fix this outer margin when the patient is in position on the operating table. If the incision is too far out, the colon may bulge in the field; if too far in, the sheath of the erector spinæ may be opened, or the fibers of the quadratus lumborum encountered. It is better to avoid both of these things.

The lower pole of the kidney is usually reached easily, but at times it was difficult to bring the upper pole well up into the wound. Sterile tape slipped around and under this upper end, acting like a lasso, facilitates this part of the operation, and was, I believe, suggested by Dr. Arthur Cabot. The incisions have been closed either in layers or by the through and through silkworm gut sutures. In two incisions rubber dam or a bit of gauze was placed in the lower angle of the wound.

The actual decapsulation was usually done by splitting the capsule longitudinally with a scalpel and then peeling it off gently with forceps and fingers. In at least one case the capsule was found to consist of two distinct layers, and when the kidney had been apparently decapsulated, another complete layer was discovered and removed from it. This second layer would have escaped if attention had not been directly called to it. If it remained behind, at least part of the aim of the operation would have been lost.

As a rule the capsule separated without much difficulty. In contracted kidneys it is much more adherent, and occasionally carries with it morsels of the cortex. As it was separated it curled back towards the pelvis, and was removed with scissors. In one case where there was much difficulty in reaching the upper end of the kidney the capsule was simply pushed back over the upper pole, and left curled up beyond it. Small wedge-shaped bits of the cortex were taken at the operation from each case for pathological diagnosis. If there was persistent hemorrhage from the kidney wound it was closed by a carefully applied mattress suture of catgut.

In two cases patients were cyanotic and more or less collapsed on the table. As before stated

[1] Read at the Annual Meeting of the Suffolk District Medical Society, April 25, 1903.

this seemed to be due to interference with respiration produced by the large rubber air cushion. This cushion is better suited to the unilateral operation. These two cases did not, however, show signs of continued shock after the operation. In fact, with the exception of one case, the absence of post-operative shock was remarkable.

Two of the five cases complained simply of "soreness in the back" on the day after the operation.

The operation was always followed by a temporary diminution in the amount of urine, but this quickly disappeared, and within a few days the amount usually exceeded that passed before the operation. An increase of blood in the urine was always demonstrable by the microscope, and in one case the urine was mahogany colored for several days; in two cases the color was not changed, and in the others it was slightly high. One patient tore off the dressings and infected his wounds, which, as a result, granulated very slowly. There was a slight infection in the lower angle of one other incision. With these exceptions the wounds healed by first intention in from ten to fourteen days. There was not in any case a marked increase of pre-existing renal elements of the urinary sediment following the operation. As above stated, red corpuscles were invariably present afterwards, or if present before, were increased afterwards. But casts and cells did not show any material numerical change. It seems certain, therefore, that the so-called ether nephritis is largely a medical scarecrow; for if it were ever to appear, it would seem that pre-existing renal disease and actual operation on the kidney should favor its development.

The cases in detail are as follows:

CASE I. Male, forty-two years; cab-driver. Father and mother died of asthma. Patient has used alcohol to excess. Had gonorrhea fourteen years ago. For past five months increased nocturnal micturition, three to five times each night. Three weeks ago edema appeared, followed by anorexia, insomnia, epigastric pain, headache and diarrhea. He gave up work one week ago. Patient gave the above history on his first appearance at the Medical Out-Patient Department in June 1, 1902. He entered the medical ward on June 3. He was well developed and moderately fat; heart was negative, radial arteries sclerotic. A few moist râles were heard in the lungs, which were dull on percussion in the back, increasing to flatness at the bases. Free fluid was present in the abdominal cavity. There was marked edema of the legs, scrotum and penis, which later extended to the back, the abdominal parietes and the face. Temperature, normal; hemoglobin, 85%; leucocytes, 10,000; red cells, 5,470,000. The urine was smoky, neutral, 1,019, and contained ¼% albumen. The sediment consisted of some normal blood, fine granular and hyaline casts with many fat drops and fatty renal cells adherent, some fatty renal and compound granule cells, and triple phosphates. Urea was 1.82%.

On June 12, not having improved, he was seen in consultation and transferred to the surgical side. He was operated by Drs. Burrell and Blake two days later. Ether anesthesia. The operation was difficult on account of the edema of the back and the large amount of fat. Both kidneys were decapsulated. There was practically no post-operative shock. He began to feel better almost immediately. The edema began to diminish in ten days, and was entirely gone in six weeks. The urine increased in amount to 150 oz. The wounds healed by first intention, except at the lower angle on the left side, which became infected and granulated. He sat up after five weeks, and was discharged on Aug. 2, 1902. At that time the urine was smoky, 1,012, acid, and contained 1/10% albumen. In the sediment was an occasional cast with fat, a few renal cells, leucocytes and blood.

He gained strength steadily and resumed his occupation. Four months later his urine was pale, neutral, 1,004, and contained 1/12% albumen. The sediment was practically the same as in August. On April 25, 1903, the patient reports that he is feeling better than ever, is strong and active; he drives a cab; his appetite is excellent. There is neither pain nor discomfort at the site of operation. He looks very well, but still takes several drinks each day. The urine is pale, with a very slight smoky tinge, acid, 1,020, and contains about 1/10% albumen. Urea, 2%. Sediment slight, consisting of a few squamous cells. Some blood and fatty renal cells; a few leucocytes; a few hyaline, fine and coarse granular casts, some with degenerated renal epithelium adherent; a few calcic oxylate crystals. The diagnosis was chronic diffuse nephritis.

CASE II. Female, thirty-nine years; housewife. This patient had been in the City Hospital several times since 1894. She had been operated once for fistula in ano, which communicated with an ulceration of the rectum, and later was operated for a tubercular proctitis, which soon returned and persisted until her death. The urine in 1894 was normal color, acid, 1,026, no albumen, but contained pus in the sediment.

She entered the medical side in July, 1902, suffering from chilly sensations, fever, dyspnea, increased frequency of micturition and edema. The symptoms had been increasing for months and continued to increase in the hospital. She was seen in consultation and transferred to the surgical side. At that time her urine was pale, acid and contained ¼% albumen. The sediment contained pus, a few hyaline and fine granular casts, a little free fat, a few small round cells, fatty renal cells and red corpuscles. Examination for bacillus of tuberculosis was negative.

She was operated on Sept. 12, 1902, by Drs. Munro and Blake; ether anesthesia. The operation was less difficult than the previous case. There was considerable shock, pain and post-operative weakness. The pain seemed to be in *front* of the kidneys, and was accompanied by tenderness. There was no rise in pulse or temperature; the wounds healed by first intention, and she sat up in two weeks. The pathological diagnosis of specimens taken at the operation was "marked acute degenerative nephritis; slight amyloid degeneration of glomeruli; slight chronic nephritis."

After the operation the percentage of urea increased from 1.13% to 1.64%, but the actual amount diminished from 13.90 gm. to 12.60 gm. She grew stronger slowly, and was discharged on Oct. 6, 1902. The urine at that time was pale, acid, 1/10% albumen, the sediment containing a considerable quantity of pus, an occasional normal and abnormal red globule, small round cell, occasional hyaline and rare waxy cast. Two and one-half months later she reported that she had not improved much, save for a slight gain in strength and the disappearance of the edema. The urine contained ¼ to ½% albumen; considerable pus, hyaline and granular casts, many renal cells and some blood corpuscles. She died on March 18, 1903. I am indebted to Dr. W. B. Bancroft, her physician, for the following notes: She was up and about her home, doing light work, until two days before her death; she had occasional edema of the face; she developed a moderate cough; her pulse became poorer, her strength failed, and she died without unconsciousness nor uremic symptoms. One month before her death the urine contained ¼% albumen and much pus; no renal elements seen. The clinical diagnosis at death was "tuberculosis of apex of right lung; tubercular ulceration of rectum; tuberculosis of kidneys." The latter was justified, in spite of the negative findings in relation to the bacillus of tuberculosis in the urine.

CASE III. Male, thirty-one years; teamster. This patient entered the medical ward of the City Hospital

on July 1, 1902, having had edema, headache and dark-colored urine for several days. His family history was negative, his previous history good; he was moderately alcoholic. After two weeks he was seen in consultation, and operation was considered inexpedient. He improved very slightly and left the hospital in September. Almost immediately the edema returned, accompanied by pain in the back and increased frequency of micturition. He was admitted to the surgical side on Sept. 17, 1902. Heart, lungs and abdomen were negative; pulse was good. Urine was pale, acid, 1,013, albumen ¼%; the sediment contained numerous hyaline and fine granular casts of small diameter, with renal cells adherent; considerable blood free and on casts; some fat and many renal cells, occasionally fatty. The quantity varied from 40 to 60 oz. Urea, 14.52 gm. Operation Sept. 26, 1902. Drs. Munro and Blake; ether anesthesia. The urine was dark colored after the operation; the wounds healed by first intention; the edema was gone in two weeks; four days later he was up around the ward, and was discharged three weeks after the operation. At this time the urine was dark, acid, ¼% albumen; the sediment contained an occasional blood corpuscle and triple phosphates. One month later he reported that he was working hard and feeling well. The urine was pale, $\frac{1}{16}$% albumen; there was an occasional cast, hyaline and fine granular; considerable renal epithelium, some with fat adherent; occasional red corpuscle.

April 24, 1903, this patient reported again; he had done heavy work every night until three weeks ago; felt stronger than ever and could lift more. He then began drinking hard and continued to do so for two weeks. He stopped because edema of his face appeared; until that time his urine was clear and he was passing large quantities. While drinking, his urine became the color of Bock beer, but is now clearing. At this date (April 24) he looks well; he has slight edema of the ankles; his appetite is good and he has gained twenty pounds. The urine is smoky, acid, 1,005, albumen ¼ + %, urea .88%; the sediment contains considerable normal blood, a few leucocytes, some renal cells with fat adherent, an occasional compound granule cell and a very few hyaline and fine granular casts. The pathological diagnosis of bits of kidney taken at the operation was "chronic glomerulo-nephritis, so-called parenchymatous."

CASE IV. Male, twenty-six years; clerk. He entered the medical ward Jan. 13, 1903, having had for four days backache, edema of ankles and dark-colored urine. His family history was negative; he had suffered from malaise and indigestion for six months. There were râles over the entire chest; general edema, the heart being negative. Urine was high, acid, 1,029, albumen ¼%; sediment contained many casts, hyaline and fine granular, with small round cells, blood corpuscles, leucocytes and renal cells adherent; a little fat and a few abnormal red cells. His edema increased and he developed nausea without vomiting; he was seen in consultation and transferred to the surgical side on Jan. 30, 1903. He was then pale, thin, the pulse poor in volume and tension; lungs dull at the bases; abdomen containing free fluid; he had also an albuminuric retinitis.

Operation, Jan. 3, 1903, Drs. Burrell and Munro; ether anesthesia. He was very cyanotic during the operation, the pulse being barely perceptible at times. He made a poor recovery from ether; his urine did not change after the operation save for the appearance of some red corpuscles. On the second day he passed 14, on the third day, 20 oz.; he was conscious; he vomited for twelve hours on the third day, but stopped after being given spirits of chloroform; he then retained milk and lime water and enemata. He lost strength and sank gradually, however, and died, without signs of uremia, on Feb. 4, 1903. Pathological diagnosis of operation specimens was "subacute glomerular (amyloid) nephritis."

CASE V. Male, twenty-nine years, admitted to the medical ward Nov. 19, 1902. His family history was good; no previous disease; he denied venereal, but admitted twelve "schooners" of beer and two whiskies daily. Two weeks before entrance he developed chilly sensations, fever, slight cough, headache, nausea and vomiting; his urine was scanty and dark; edema appeared in the face, later in the hands, abdomen and legs; there was anorexia and some diarrhea; he had been in bed for three days. He was pale and fat; the heart was negative and there were râles at the bases of both lungs. The urine was smoky, acid, 1,026, albumen ⅛%; the sediment contained very many casts, hyaline and granular, with renal cells, fat drops and blood globules adherent; few squamous epthelium; neck of bladder, small round cells, leucocytes and red corpuscles. The white count varied from 8,000 to 12,000; urea from 2% to $\frac{1}{10}$%. The albumen ranged from ¼% to ½%, and the quantity of urine from 20 to 50 oz. He was a difficult patient to manage, refusing treatment at times. His condition did not improve; he was seen in consultation frequently, and was transferred to the surgical side on Jan. 24, 1903. At this time the urine was normal in color and about 50 oz.; otherwise practically unchanged since entrance. There was dullness in the back to the angles of the scapulæ; respiration and fremitus diminished; abdomen distended and containing free fluid; back and scrotum very edematous; albuminuric retinitis.

Operation Jan. 27, 1903, Drs. Burrell and Munro; ether anesthesia. The wounds were drained with rubber tissue on account of bleeding and free discharge of serum. He recovered well from the operation, but two hours later went into a moderate collapse, due to hemorrhage from the wounds; this was controlled by fresh dressings and a tighter swathe. For next two days he was very noisy and violent; he vomited frequently, and tore off his swathe; he then gradually improved. The amount of urine diminished and then increased, the sediment remaining unchanged; the edema gradually diminished. The wounds became infected as he continued to tear off the dressings from time to time. Five weeks after the operation he developed a broncho-pneumonia, which almost killed him, and which has left him with a cough and râles in his lungs. Later he was about the ward in a wheeled chair. On April 14 his urine was pale, acid, 1,020, albumen ¼%; urea 1.70%, 18.87 gm; sediment, many fatty granular renal cells, normal and abnormal blood globules; fine granular casts of large dimaeter, with epithelial cells, fat drops and blood adherent; a few hyaline, epithelial and fatty casts. His face was pallid, his appetite poor and his edema considerable. He was discharged to Tewksbury four days later. The pathological diagnosis of the operation specimens was "subacute glomerular nephritis."

Edebohls' recent article appeared in the *Medical Record*, March 28, 1903. In it he reports 51 cases, of which he has been able to trace all but 3. There were 47 operations on both kidneys, and 4 on one kidney only. Seven died within seventeen days after operation; 7 died in periods varying from two months to eight years; 2 do not show satisfactory improvement; 22 are in various stages of satisfactory improvement at periods varying between two and fifteen months after operation; the urine of several of these is free from albumen and casts. Nine patients were cured of chronic Bright's disease and remain cured at periods after operation varying from twenty-one months to ten years. Edebohls says: "To be classed as a cure, the following conditions must be fulfilled: the urine must remain free from albumen and casts, and the output of urea be normal, or approximately so, for a period of at least six months after the verification of the disappearance of albumen and casts, and the patient must be free from the symptoms of chronic Bright's disease from which he or she formerly suffered."

This is a sufficiently rigid standard of cure. Judged by it, none of the five cases here reported are cured; two of them are free from symptoms

and doing hard work as well or better than before their attacks; abstinence from alcohol on the part of these men might be followed by the disappearance of albumen and casts from the urine. Unfortunately, however, such abstinence is not likely to occur, and these two cases must be described as much relieved but not entirely well.

RUPTURE OF THE QUADRICEPS EXTENSOR FEMORIS MUSCLE.[1]

BY HALBERT G. STETSON, M.D., GREENFIELD, MASS.

IT occasionally happens that the country practitioner runs across something rare or at least unusual in a medical or surgical way — a condition which perhaps he recognizes, but for the description and relief of which he looks in vain in his limited library. He may, perhaps, find some mention of the particular condition with which he is called upon to deal, but for any real practical help or aid he may look in vain. His own library fails him because not sufficiently extensive and he is out of reach of the larger medical libraries of the city. He is then called upon to make use of his own talents and common sense, and his results will depend very largely upon his exercise of those qualifications.

Rupture of the quadriceps extensor femoris muscle is one of these unusual conditions. An accident at least not common, and many surgeons in large practice would, I believe, say rare. At least but little mention is made of the subject in modern textbooks of surgery, and many of them do not speak of it at all. Agnew, in his "Principles and Practice of Surgery," third edition, says he has meet with but two cases, and his experience, even at the time he wrote that, was a very extensive one. Connor, in Ashhurst's "System of Surgery," speaks in a general way rather briefly of rupture of muscles, but does not go into the details of rupture of any particular muscle or group of muscles. Dennis does not mention the subject at all. The "American Textbook of Surgery" speaks in a general way of muscular rupture, as does Da Costa. Wyeth in his textbook, and Monks in the "International Textbook of Surgery," allude particularly to rupture of the quadriceps and to its etiology, symptomatology and treatment. On the whole, the knowledge to be gained by the general practitioner from those textbooks most likely to be in his library would be rather small.

As I have said, rupture of the quadriceps extensor muscle is not a common condition. It is most often of traumatic origin. That is, the patient is going down stairs, or down a steep incline, looses his footing, and in his effort to save himself strongly contracts his quadriceps, which was previously very firmly contracted, with the result that it ruptures, or the patella is broken; and the determining factor may be comparative weakness of the muscle or tendon. Konig, quoted by Klein, describes two ways in which this rupture may be produced. Either the actively contracted quadriceps is suddenly strongly stretched, as when one descending a mountain slips and falls backward; or the passively stretched muscle undergoes an active contraction as when one falls over a step. The weight of the body presses the thigh against the leg, forming a very acute angle at the knee joint. The stretched quadriceps contracts to avoid overstretching, and a ruptured quadriceps tendon or fracture of the patella results. Cases of rupture of the quadriceps, as of other ruptures of the body, have occurred following typhoid fever and other prolonged pyrexias, from slight strain only, and without the knowledge of the patient; but of these I shall say nothing. Certain factors, however, have at times seemed to play a part in producing weakness of the muscle fiber, rendering the rupture easier than would seem to be normal. Alcoholism and arteriosclerosis would naturally be looked upon as such factors. Evidences of a diseased condition of the muscle itself have seldom been found. Maydl reports fatty degeneration of the muscle in one case. Hafeman found tabes dorsalis in two cases. Kohl and Wunsch saw cartilaginous bodies embedded in the tendon. Kohl found beside three solid masses in the tendon, also an analogous body free in the joint, and he considered the cause to be a chronic arthritis. Wunsch found a cartilaginous formation on both sides and diagnosed with probability an exostosis of the tendon. In a case reported by Vulpius there was very marked fatty degeneration of the tendon confirmed by microscopical examination; but these were only single and unusual cases. Most of the cases examined show no pathological or degenerate change whatever.

It seems to be most frequently met with in males. In ninety-eight cases collected by Walker, ninety-one were males and seven females. This great preponderance is no doubt due to the greater muscular activity of life followed by the male sex. It occurs slightly more frequently as age advances, the majority of the cases reported being over fifty years of age.

Concerning the location, there seem to be no factors which tend to make one limb any more liable to this rupture than the other. It seems to occur as frequently upon one side as upon the other. Cases have been reported where both muscles have been ruptured simultaneously; and both muscles have been ruptured separately, an interval of several months or several years intervening.

The point of rupture is most apt to be at the upper margin of the patella, although it often occurs higher up. In its relations, this muscle lies immediately over the joint cavity of the knee, and when the rupture occurs at the upper margin of the patella, the joint capsule is very apt to be opened. Walker says that the joint capsule extends upwards behind the rectus tendon for a distance of 5 cm.; and that rupture of the muscle at any point within this distance is very liable to involve the joint.

[1] Read before The Massachusetts Medical Society, June 9, 1903.

The occurrence of rupture is usually indicated by a sudden sharp, stinging pain, accompanied by a snapping sensation as of something giving way, and associated with complete loss of function if the rupture be complete; if not complete, if the lateral portions are still intact, or if a portion of the fascia is still intact, some power of extension will still remain. If seen soon after injury, the deformity is characteristic. The patient is unable to extend the leg, the upper edge of the patella is felt and is freely movable in every direction except upward; there is a marked depression above in which the condyles of the femur can be plainly felt. Above this depression is a tumor caused by the retracted muscle. There is but little pain usually, and only moderate tenderness. There may or may not be, coming on early or late, discoloration of the skin produced by extravasated blood. Extension and flexion of the leg to an angle of 45° cause little pain. Seen later, that is, from one to fourteen days after the injury, the gap so noticeable above the patella at the time of the traumatism has become filled in with extravasated blood and is much less noticeable.

The diagnosis should not be difficult in cases seen early. The loss of the power of extension of the leg, patella easily made out and movable in all directions except upward, a depression admitting one or more fingers above the patella; these objective symptoms, together with a history of muscular effort and the subjective symptoms of sudden pain and a sensation as if something had snapped, would, seemingly, make the diagnosis easy. McCosh believes, however, from a study of the reported histories of such cases, that in many of them the injury was overlooked because the examining physician was not alive to the possibility of such an accident.

And now comes the difficult problem of all to solve. How shall this injury be treated? Shall we rely upon mechanical means to bring about coaptation with the hope of a firm, fibrous union and a nearly functionally perfect leg? Or shall we invite the dangers attendant upon surgical manipulation of the knee joint, and cut down upon the ruptured muscle, bring the ends into opposition and stitch them with some suitable material?

Other things being equal, the operative method would seem to be the preferable method in the hands of the skilled surgeon and under favorable surroundings. Maydl, in fifty-six cases of complete rupture of the quadriceps, states the results in forty as follows: In twenty-four, or 60%, complete recovery followed; nine of the remainder acquired a useful leg; the other seven were unsatisfactory. Walker states that of twenty-three complete ruptures of the quadriceps in which he was able to give results, in sixteen, or 70%, complete recovery followed; in five a useful leg was obtained; and two cases were unsatisfactory. Compare this report with Walker's report of his operative cases—twenty-one cases so treated and nineteen, or 90%, complete recoveries.

Walker also compares the time occupied in bringing about complete recovery by the two methods. In speaking of his series of twenty-three cases of complete rupture, treated by the mechanical method, sixteen, or 70%, made a complete recovery. Of these sixteen cases, 18% recovered in three months, 31% in six months, and 50% in one year. Of his series of twenty-one cases treated by the operative method, nineteen, or 90%, made complete recovery. Of these nineteen cases, 56% recovered in three months and 100%, or the total number, recovered in six months, showing a large saving of time to the patient by the operative method in skilled hands.

Unfortunately, however, rupture of the quadriceps extensor muscle does not always occur in the young, strong, vigorous adult, the kind to whom you look for favorable operative results. I have before spoken of the fact that a large number of these cases occur after the age of fifty years. From that age on we look for degenerative changes — arteriosclerosis and its very common accompaniments, tense, wiry blood-vessels, cirrhotic kidneys, enlarged prostate, to say nothing of the greater liability supposedly of failure of union of the approximated ends.

Again, it is not always possible to bring about a meeting between the patient suffering from the injury under discussion and the skilled surgeon.

Under these circumstances it would seem to be perfectly proper treatment for the general practitioner to at least try the effect of the mechanical method of treatment. Many of us would certainly hesitate to molest the knee joint unnecessarily. McCosh, who cannot in any sense be accused of favoring the mechanical method of treatment, in his paper upon this subject advises against operative interference unless conditions are most favorable, believing that the non-operative plan of treatment should be tried, at least until more favorable conditions can be obtained. And he further says that a delay of several weeks does not contra-indicate the operation. I believe there is one danger from non-operative treatment which must be thought of, and which might become troublesome unless guarded against,— that is, inactivity atrophy of the quadriceps But early massage and passive motion would probably, to some extent, delay if not prevent this change.

All agree that in cases of partial rupture in which the lateral portions of the muscle are still intact, the mechanical treatment is all that is necessary. Most men, I believe, are in favor of mechanical treatment in cases where the distance between the divided ends is not more than one inch, and where the joint has not been opened. In those cases where the distance between the divided end is more than one inch, or where the joint has been opened, operation would seem to be the proper course to pursue; but even here the general condition of the patient would be a large factor in finally determining

upon the proper plan of treatment. And in those advanced in years and presenting the changes incident to age, even there the mechanical method of treatment might be thought advisable.

Particular care should be given to the application of the mechanical method. The patella should be pulled up as far as possible, and held in place by adhesive strips. The leg should be bandaged from the ankle to the patella, care being taken to have the bandage reinforce the plaster strip as far as possible. Beginning above at the upper portion of the thigh, bandage downward firmly, the object being to push down the retracted end of the muscle into nearer apposition with the patella. A long, posterior splint extending from the ankle to the gluteal fold should be applied and the leg strapped firmly to it. Cold applications to the knee if there is much extravasation of blood, foot elevated about six inches above the level of the pelvis. After five or six weeks, massage. After eight weeks, passive motion of joint and crutches. The time of recovery based upon reported cases should be expected in from three to twelve months.

The operative method consists in cutting down upon the separated ends and uniting them, either with silk-worm gut, catgut, kangaroo tendon or silver wire. If insufficient tendon remain attached to the patella, then drilling through the upper portion of the patella and attaching the upper fragment to the patella. Elevated position of the foot for two or three weeks, passive motion, etc., as with mechanical treatment.

Walker concludes his admirable paper with six conclusions, four of which would seem to be most useful suggestions for the general practitioner in deciding upon the proper method of treatment for this particular injury:

"First. In recent cases in which there is not much effusion, where the joint is apparently not opened, in which the separated ends can be approximated and retained by suitably adjusted pads, the mechanical treatment may be favorably considered. In the hands of an intelligent practitioner, this method may be expected to bring about a complete recovery in the larger number of cases. From nine to twelve months will be required to re-establish fully normal functions.

"Third. The skilled aseptic surgeon who promptly resorts to the operative method in suitable cases, though age and vitality of each patient must be most carefully considered, may quite reasonably hope to obtain a better result in the larger number of patients, and save his patient three to six months' time.

"Fifth. Where the separation is greater than one and a half inches, or where the case has not recovered under mechanical treatment, the operative is indicated.

"Sixth. As the length of time required for treatment is a very important consideration, so the operative method, which has diminished this period and also succeeded in a large number of cases without increasing the danger, will be more often indicated and more frequently applied in the hands of the skilled surgeon."

My attention was particularly called to this condition by the following case: S. B. S., retired, seventy-one, married, never ill. On Sept. 7, 1902, in going down stairs his slipper caught on the stair and he was thrown forward. He made a strong effort to save himself, and felt something give at his knee. Upon getting up he was unable to stand upon the leg, although the effort did not cause severe pain. The knee was "wobbly," as he expressed it, and uncertain; slight swelling occurred at once about the knee. Seen one-half hour after the injury. Left knee somewhat swollen; swelling not confined to the synovial cavity. Patella drawn downward about half an inch. Immediately above the patella is a depression allowing two fingers to be laid in; condyles of the femur plainly felt; above the depression is a moderate enlargement of apparently muscular tissue. Flexion, extension, latero-flexion, not accompanied by much discomfort. Patient can flex, abduct and adduct, but cannot extend the leg. Treatment, posterior splint applied, with a compress of lead and opium wash, moderately firm bandage. On the 8th the patient was seen in consultation by Drs. Twitchell and Zabriskie of Greenfield in reference to the advisability of adopting the operative plan of treatment. In view of the fact that the patient was the victim of some arteriosclerosis, and had for some time had some urinary retention due to an enlarged prostate, it was deemed best to try the mechanical treatment for a time, having in view the operative plan of treatment at some future time, if satisfactory results were not obtained by the mechanical. The patient was allowed up in a wheeled chair. The leg was kept in splints until the last of October, when massage and passive motion were begun. On Nov. 1 the patient was walking about with the posterior splint still on. Without the splint he can bend the knee and has some power of extension. Ordered continuance of passive motion. On the 28th of January, 1903, examination shows extension to be strong and forcible. Is able to kick vigorously; motion is good and unimpaired. As compared with the opposite leg, it would seem that he had from 75 to 80% of normal function. Patient says that he can see improvement still going on. Patient shows no lameness, climbs in and out of carriage easily and attends to his usual duties apparently as easily as before the accident.

DISCUSSION.

DR. S. J. MIXTER of Boston: I should be happy to say something on this very interesting paper, but the fact is I have never had a case of rupture of the quadriceps extensor; that is, a complete one or anything near complete. I have had par-

tial ruptures. I have seen several ruptures in the practice of other men. None of these have been operated on; they have been treated mechanically with good results. A distinguished member of the Massachusetts Medical Society had such an accident at the time I was a student. He was treated by Dr. Bigelow, and got a very good leg. I think I am correct in saying Dr. Bowditch had that accident by jumping from a horse-car. At that time, of course, operative procedures were not so common as now, and on account of his age, at any rate, it was best to follow a conservative line of treatment. He made an excellent recovery. Slight ruptures I have seen. It seems to me that ruptures of the quadriceps extensor tendon are very like fractures of the patella. In certain cases of fractured patella we get excellent results without operation. Those are cases in which the fascia is not widely torn, where the fragments are not separated. It is not the fracture of the patella so much as tearing of the fascia which causes trouble, and if we have only slight separation of fragments either of the patella, which is only a sesamoid bone in the course of the tendon, or the tendon itself, mechanical means will be able to give good functional results.

DR. H. WARREN WHITE of Roxbury: This paper is very interesting to me now just, after having taken care of a case similar in many ways. A man of seventy in going down steps thought there was another step. He made an attempted step and recovered himself, but felt, as he described it, as if he had "torn his pants." There was a giving way of something, he looked down and found he could not manipulate his leg, could not extend it at all. He was completely incapacitated, and brought home and treated with plaster-of-Paris bandages. But the curious part of our case was, that at the end of ten weeks, after removal of the plaster-of-Paris bandage and what appeared to be a complete and satisfactory result, and wearing an ordinary rubber bandage, he was in the stable attending to some duties when with a slippery floor under him his foot gave way suddenly and the same accident happened again, absolutely the same as far as the gap was concerned; perhaps not quite as extensive, that is, the gap was not quite so wide as at the first time, but there was the same inability to extend the leg. He is at the present time lying in bed with a plaster-of-Paris bandage on and we are hoping, of course, for as good a union as before. I had a consultation in this case and the same conclusion against operation was arrived at that Dr. Stetson speaks of. Our patient was old. He also had urinary trouble, and there was the slight arteriosclerosis of which he speaks, and signs of the same muscular weakening or degeneration which probably permits such an accident to occur in these cases.

THE chair of anatomy of the Woman's Medical College of Philadelphia is vacant, through the recent death of Dr. Parish.

Clinical Department.

REPORT OF A CASE OF APHASIA AS A COMPLICATION OF MEASLES.

BY WARREN R. GILMAN, M.D., WORCESTER, MASS.

THE patient, a strong, healthy boy of nine years, was out of doors as usual Nov. 10. He complained of not feeling well that evening, ate little, and was rather restless during the night. About thirty-six hours later the rash was well developed, and it was evident that the disease was measles. The course of the disease was not remarkable in any particular during the next three days. There was a profuse eruption, moderate fever, but no delirium. On Nov. 15 the eruption was fading and the patient felt so well that he was allowed to sit up for a short time. During the night he became restless and delirious, and the nurse had some difficulty in restraining him.

When I saw him on Nov. 16 he was very dull, apathetic, and could not be roused to give any sign of intelligence. For twenty-four hours he was apparently unconscious of his surroundings. There were several brief periods of mild excitement, but there were no convulsions. There was no paralysis. He passed urine and had several evacuations of the bowels in bed without giving the nurse any warning, but these acts were accompanied by straining efforts and were not strictly involuntary.

In the afternoon of Nov. 17 he sat up in bed and looked about the room. He was confused and dull, and, although it was possible to attract his attention by speaking in a loud voice, he showed no evidence of any comprehension of words or signs. On the next day, Nov. 18, he tried to talk, but his efforts resulted only in the endless repetition of "Mother, mother, mother."

On Nov. 19 his expression was much more intelligent, although there was still some confusion and astonishment in his face. He saw the people in his room, but I think he did not recognize the individuals. An occasional, explosive "Gee!" expressed his feelings very well. The only other word at his command was "Mother"; and in the recurring utterance of this word his pauses and inflections indicated that he was trying to express ideas and thoughts. At one time the inflection indicated a question; at another, an assertion. The question was the more frequent form, and it seemed quite plain that he was trying to ask why we could not understand him. He evidently thought that he was talking intelligibly and did not notice his deficiency. He understood and obeyed the request to lie down. Used the bed pan. Examination of urine negative. Rash entirely gone. In drinking milk from a cup, he sipped slowly, filled mouth and then had difficulty in swallowing; several times the milk was belched from mouth but was not regurgitated through the nose. This accident made him angry, and he expressed his disgust very plainly by gestures and an emphatic "Gee!"

On Nov. 21 he was able to understand questions and orders very well, but was still somewhat dull. Had added several words to his vocabulary, but was not able to form sentences. On looking out of the window and seeing one of the housemaids, said, "Hello, Kate." Understood the account of a football game which was read to him. Passed his time in kicking a football about the room; made the nurse understand that he wanted his shoes for this sport; hummed a tune correctly; did not attempt to sing. Pupils equal and react normally. Knee jerks normal. Babinski reflex not present. No paralysis of any kind; swallowed food easily.

Nov. 23, bright and wide-awake. Understood everything read or spoken to him. When a column of several figures was added up incorrectly he detected the error at once. Wrote his name for the first time. Used more words and would get part way through a sentence before coming to grief. Did not use wrong words, but came to a stop when he could not get the word he wanted. Attempts to get him to repeat words and to write words from copy or dictation were not satisfactory. He was conscious of trouble, and would not expose his weaknesses. Nov. 28, read stories to a younger brother and hesitated very little. Wrote from dictation or copy very well. Improvement continued, and on Dec. 1 he was practically well.

The measles was not severe and the rash came out quickly. On the third day the temperature reached the highest point, 104.5. It declined quickly as the rash faded and on the fifth day was 100. During the night he became very restless, but soon fell into a dull, unconscious state. There were brief periods of excitement, but as a rule he lay in bed with eyes open, understanding nothing said to him and seeing nothing. There was complete inhibition of the auditory and visual centers and also of the higher speech center. There was no paralysis of the muscles of face, lips or extremities.

Restoration of function began in the visual and auditory centers, as is the rule, I believe, and he gradually regained the power of visual and auditory perception. The function of these sensory centers was completely restored before recovery of the higher kinesthetic centers. His first attempt at speech resulted only in the recurring utterance of the one word "Mother!" and an occasional exclamation, "Gee!" or "Oh!" For two or three days these were the only words he could utter. He received definite normal impressions on the visual and auditory centers, and very soon showed that he wished to express his ideas and wishes. This he was unable to do either in speech or writing. His vocabulary grew gradually and there were no mistakes in the use of words. When he could not get the word he wanted, he simply stopped. There was inability to read or write. He soon recovered the power to read and to understand figures, and could read a newspaper before he could write more than his own name. It is interesting to note that he hummed a tune correctly before he used complete sentences.

Severe disturbances of the nervous system occur very frequently in nearly all the acute infectious diseases, coming on as a rule late in the disease or during convalescence. There may be a gradual development of a general peripheral neuritis or a sudden attack of unconsciousness from which there is speedy recovery, disclosing the presence of various forms and degrees of paralysis. The paralysis of muscles of the extremities, face or throat in diphtheria is the most familiar example. It is now generally believed that these palsies of diphtheria are due to a general or peripheral neuritis caused by the toxin of the disease.

In typhoid fever there are frequently severe nervous disturbances. Hemiplegia and facial and hypoglossal paralysis occur. Postmortem examinations have sometimes shown hemorrhage, embolism and thrombosis of cerebral vessels. At times aphasia has been observed in connection with these severe complications.

Some writers feel warranted in grouping certain cases of very slight peripheral paralysis with aphasia, or cases of aphasia alone, into a distinct class. These cases recover quickly and are said to be the result of some slight and temporary change in the cortex of the brain, probably congestion or edema. It seems to me more reasonable to say that such symptoms are caused by the direct action of a toxin upon the nerve cells in the sensory and motor centers of the cortex. There may be some gross change like congestion or edema as a result, or there may be no visible change whatever. In scarlet fever, paralysis of peripheral or cortical origin occurs less frequently than in diphtheria or typhoid fever.

Various forms of paralysis have been noted in whooping cough, and they have usually been looked upon as the result of vascular changes. In the *New York Medical Journal*, June 6, 1903, C. J. Aldrich reports a case of peripheral neuritis showing slight paralysis of legs, hands and palate. He considers the cause of the neuritis to be the toxin developed in the course of the acute disease.

It is stated in textbooks that severe or mild nervous disturbances may follow measles; but I have not found reports of any specific cases during recent years. Writers usually refer back to the monograph of Clarus written in 1874, and in that article very few cases are cited.

In the case which I have reported I believe that the sensory and motor aphasia was caused by the action of the toxin of the disease, measles, upon the centers in the cortex of the brain. Hemorrhage or embolism seem quite improbable. The measles was not severe and the cough was mild in character. The patient was a healthy boy whose heart, kidneys and blood vessels were normal. There was no paralysis of extremities or face; and the paralysis of the throat, if it was paralysis at all, was extremely mild and lasted but a few hours. Recovery from the aphasia was prompt and complete.

Medical Progress.

REPORT ON OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

TUBERCULOSIS OF THE PLACENTA.[1]

WITHIN the past few years several cases of placental tuberculosis have been described. The first case, demonstrating the transmission of tubercle from mother to fetus, was described by Schmor and Birch-Hirschfeld. The patient was seven months pregnant, and died of acute miliary tuberculosis. A dead child was delivered by Cæsarean section. In the blood of the umbilical veins, capillaries of the liver, intervillous spaces and vessels of the chorionic villi, tubercle bacilli were found. Pieces of tissue removed from the fetus and introduced into rabbits produced typical tuberculosis. Lehmann[2] described a case where the placenta from a case of acute tuberculosis contained tuberculous nodules with typical bacilli, and similar cases have been recorded by Kockel[3] and Kynoch.[4] In all those cases the fetal portion of the placenta was chiefly affected. The surface and stroma of the villi contained granulation tissue with tubercle bacilli. The vessels of the villi were in some cases obliterated, and the bacilli were supposed to have reached the interior of the villi from the intervillous spaces through an epithelial defect on the surface.

Runge[5] reports a case where tuberculous changes were found in the decidua serotina. Patient, aged thirty-two, died of general tuberculosis. On the posterior wall of the uterus, which contained a four months' fetus, gray nodules were found. The appendages were normal. Pieces of placenta were cut and stained. A few tuberculous masses with giant cells were found in the chorionic villi. In the decidua, and reaching as far as the glandular layer, there were well-defined tuberculous foci. No tuberculous change was found in either the decidua vera or reflexa. Necrotic changes and abundant hemorrhages, resulting in detachment of the villi, would account for early abortion in those cases as contrasted with the cases where the tuberculous changes were chiefly confined to the villi.

Warthin[6] and Cowie report the case of a woman with acute miliary tuberculosis, in whom abortion at the seventh month occurred the day before death. Placenta and fetus showed no macroscopic lesions, but the microscopic examination showed that the placenta was filled with thrombi, composed of red blood cells or possibly of blood plates, which thrombi contained great numbers of tubercle bacilli. The thrombi occurred chiefly in the intravillous spaces. Of interest was the behavior of the syncytial cells, which seem to have been especially resistant to the tuberculous process, since in many instances they had grown over and around the thrombi. The giant cells of the thrombi Warthin thinks were composed of leucocytes. Great numbers of the tubercle bacilli were found in the blood vessels of the liver of the fetus. The fetal tissues seemed especially resistant to the growth of the organism. Warthin believes that congenital tuberculosis is possible, and should be considered as a possibility. In this case the presence of the bacilli was demonstrated both in sections and in inoculation experiments.

INCARCERATED GRAVID UTERUS REPLACED BY THE COLPEURYNTER.

Albert[7] reports five cases in which he has had marked success in replacing the retroverted incarcerated pregnant uterus by means of the rubber colpeurynter inserted into the vagina. He first empties the bladder by a catheter, and he emphasizes the importance of doing this in all cases before making a diagnosis of retroversion. The patient is placed on her side and the colpeurynter introduced, and slowly filled with sterile water. Usually a few hours only is necessary for replacement, but if improvement does not shortly occur, more fluid may be introduced to secure further distention. The uterus is slowly raised without pain or injury to the contents. The bag may be left in over night if necessary. One of his cases was replaced within two hours, but had been incarcerated for over three weeks. He has never yet failed to relieve the condition without difficulty. A pessary may be inserted to control the uterus after replacement if the pregnancy is under four months.

PREGNANCY AND LABOR FOLLOWING NEPHRECTOMY.

Bovée[8] notes the infrequency of recorded cases of pregnancy and labor following upon nephrectomy. He mentions Steinheil's case, where the left kidney had been removed for tuberculous disease at the second month of pregnancy, associated with pus and blood in the urine. In this case the urinary symptoms improved, and the patient was delivered at full time of a healthy child. She died two years later from recurrent tuberculous disease.

Schramm reports the case of a woman, aged twenty-five, who had the right kidney removed for hydronephrosis. Five weeks later she was discharged from the hospital with a slight amount of pus in the urine. The left kidney was normal. She became pregnant four years later, and had a normal confinement, the urine being then free of pus. He refers to Fritsch's case, where nephrectomy for ureteral fistula had been performed on a patient who afterwards became pregnant and had a normal confinement, with subsequent good health.

Bovée's own case was one of complete nephroureterectomy for pyonephrosis, renal calculi and miliary abscess in the ureter. She was

[7] München. med. Woch., March 24, 1903.
[8] Am. Gynæc., vol. i, No. 5, and vol. ii, No. 4.

confined a year later, labor being normal, the child weighing 10½ pounds. The third day after delivery she complained of great abdominal pain, referred chiefly to the course of the left ureter, associated with rise of temperature. Six months later the urine contained a considerable amount of albumin.

Baldwin [9] also remarks on the frequency of nephrectomy and the infrequency of reported cases of pregnancy and labor following the operation. He reports two cases of his own, one of which became pregnant three years after nephrectomy and the other eighteen months. Both patients had normal pregnancies and confinements with normal urines. He concludes, therefore, that the prognosis of pregnancy following nephrectomy is by no means unfavorable.

The question of vital importance in these cases is the permanent effect of pregnancy and labor upon the remaining kidney. In the case of Steinheil the patient succumbed to the extension of the tubercular process to the remaining kidney. Whether pregnancy and labor caused this extension in part or entirely could not be determined. Certainly the woman had not suffered from renal trouble during the seven years following nephrectomy, but died one year and nine months after delivery. In Schramm's case no history of the patient subsequent to her discharge from the hospital was given. In Bovée's case the condition of the remaining kidney did not seem to be worse than before pregnancy. He has little doubt, however, that pregnancy and labor following nephrectomy seriously jeopardized the life of the patient; that the renal complications must necessarily be greatly increased, and therefore induction of premature labor is necessary.

SECONDARY PERINEORRHAPHY IN THE PUERPERAL PERIOD.[10]

Bohnstedt [11] reports ten cases of secondary perineorrhaphy, performed during the puerperium, within two weeks after labor. In eight of these cases sutures were applied immediately after labor, but no union was obtained. In the other two cases no sutures were applied after labor, and the patients were operated on on the fifth and the thirteenth days respectively. In no case was there a complete failure after secondary perineorrhaphy, although a relative failure resulted in four cases, of which three were referable to suppuration in the catgut sutures. The author operated upon all the cases of perineal tears that were found to be incompletely healed, and did not select cases in which the wound was covered with fresh granulations. He did not pay special attention to this circumstance, because he denuded the wounded surface very carefully, removing any false membranes that had formed. Evidently germs reached the denuded surface from these false membranes. Hence, the rule should be that a secondary perineorrhaphy should never be performed until the wounded surface has cleaned up completely. The operation must also be avoided if the woman is showing even a slight elevation of temperature, as its success is not probable in such cases. The author recommends the use of cocoaine as a local anesthetic in these operations.

His results are not sufficiently alluring to tempt one to operation at such early periods, unless unusual conditions appeared to demand it. It would seem better under ordinary circumstances to postpone the secondary operation for a few weeks until the tissues are in such shape that a cure could be reasonably assured.

ANESTHESIA IN LABOR.

Von Steinbuchel [12] thinks that the ideal anesthetic during labor is one which deadens all pain, yet does not influence the uterine contractions. If it be inhaled it must not be dangerous either to mother or child nor produce atony of the uterus after expulsion of the ovum, as frequently follows use of chloroform.

Such an anesthetic, he thinks, he has found in the scopolamin-morphin mixture. The value of this mixture lies in the action of small sub-toxic doses of these drugs, which possess antagonistic properties. Von Steinbuchel used scopolamin (hyoscine) hydrobromate in doses of .3 mgm. combined with morphin muriate .01, injected subcutaneously. If he does not get the desired effect from the first dose in one half hour he repeats it. From his use he advises its acceptance as a means of allaying all nervousness. In some cases he combines it with inhalations of ether or chloroform if the pains are very severe. In no case has he had bad effects.

Among the agents employed for short general anesthesia in obstetrical practice the bichloride of ethyl has been greatly advocated. Von Hacker was the first to use this agent as a general anesthetic, and in a series of 66 cases he found that complete anesthesia resulted in sixty to ninety seconds and that vomiting and subsequent headache were lacking or very insignificant. Soon after Lotheisen reported a series of 170 cases in which vomiting occurred in 18 and the period of excitement in 13. Other observers have recorded similar results from its use.

Lepage and Le Lorier report fourteen cases in which they used chloride of ethyl as an anestheic in obstetric operations, and from their experience they can recommend it highly. They found that they obtained anesthesia in thirty to sixty seconds. This continued for four minutes without a second administration. The return to consciousnesss, once begun, progressed rapidly, and was not followed by vomiting. They claim that it can be used very advantageously when a rapid and urgent extraction of the fetus is necessary, or where manual delivery of the placenta becomes necessary, or where a ruptured perineum must be sutured. Their

[12] Obstetrics, Peterson, April, 1903.

method of administering this anesthetic is similar to that of chloroform or ether.

Wild [13] reports the use of scopolamine and morphin for narcosis in eight operations. Anesthesia follows at varying intervals and lasts from seven to fourteen hours. In seven cases the effect was good. But there is danger of morphin intoxication, as the bad results in the last case show. Therefore Wild sounds a note of warning against the general employment of this method. The dosage is minutely described.

GLYCOSURIA GRAVIDARUM.

Ruoff [14] says that this condition is not so uncommon as it is unrecognized, owing to neglect to examine for it. The condition or its treatment does not differ essentially from glycosuria in the non-gravid subject. Its frequency is purely a matter of speculation. It may develop during pregnancy, or pregnancy may occur during glycosuria. His conclusions are as follows:

Glycosuria gravidarum may arise at any stage of pregnancy. It is not so serious as when diabetes antedates pregnancy.

It may disappear in one pregnancy and reappear in another, and end fatally after successive attacks. It frequently arises during parturition, but is of no great importance.

Labor is not materially affected, other conditions being equal. Pregnancy is most likely to be interrupted. It is very destructive to the fetus — more so than syphilis. Maternamortality is nearly 50%. Diabetics should not marry. Death is usually by coma, no case of eclampsia having ever occurred in a diabetic.

UTERINE ACTION.

Stephenson[15] discusses the subject of uterine action in its bearing on the management of labor. He combats the statement that the first point in the prevention of post-partum hemorrhage is not to deliver in the absence of uterine contraction, on the ground that the main factor in preventing hemorrhage is retraction of the uterus, a force independent of contraction. He says that the term "retraction" was introduced by Duncan, and was held to be a useful term to designate the condition of the walls of the uterus whereby its capacity was permanently lessened in proportion to the diminution in bulk of its contents. But while Duncan believed retraction to be a force independent of contraction, although like it, dependent on the action of muscular fiber, the general opinion was and is that retraction was dependent on contraction, and was the permanent shortened condition of the muscle after contraction when the active contraction had passed off. On this theory, retraction without contraction is impossible, and to deliver except during contraction must be unsafe. Stephenson's view is that retraction is a force small in amount, but continuous in its action, independent of contraction, dependent upon the muscle tone of the uterus, the retractility of the peritoneum and possibly on the action of the yellow elastic fibers. Retraction counteracts the force of the blood pressure, tending to expand the uterus, and must therefore be itself a force. The tonus of healthy muscle might be enough to counteract the blood pressure, but it is easy to show that a stronger force than this is in time exerted, either by attempting to turn after the liquor amnii has for some time drained away, or by trying to pass the hand through a retraction ring. The resistance offered is not of the nature of a contraction, tetanic or otherwise, for when once established it is permanent. The action of the peritoneum is considered. The peritoneum is closely applied to the uterus in the parts where active retraction is manifested, and itself retracts as the uterus diminishes. The expansion of the peritoneum with the gradual increase in bulk of the uterus is an example of the plasticity of inelastic substances whereby they spread out under the influence of a small force steadily applied. That it is not of the nature of elastic expansion is proved by the fact that the tension of the membrane is not increased. Nor can the diminution in surface extent of the peritoneum with the emptying of the uterus be considered as an elastic recoil; retraction describes the movement and implies no theory as to the nature of the force. This property of the serous coat enables it to take a share in the retraction of the uterus, and there is no reason to believe that its action is affected by exhaustion of the muscular tissue. The conclusion of practical importance is that retraction as a force is continuous and not intermittent, and that its action may be relied upon in the absence of contractions. Examples are given in which retraction reduces the cavity of the uterus in the absence of pains: (1) In Cæsarean section, where both child and placenta are removed without waiting for a pain; (2) in various complications of pregnancy where it is deemed advisable to empty the uterus artificially without first inducing labor; (3) in excessive hydramnios the membranes are ruptured, and the author always finds that the uterus retracts steadily without any evidence of contraction; (4) in severe hemorrhage with retained placenta the author invariably introduces his hand into the uterus and removes the placenta, and the hand is kept in the uterus until contraction occurs, or more frequently until the cavity lessens by steady retraction.

(To be continued.)

[14] Amer. Med., April 25, 1903, p. 665.
[15] Journ. Obst. & Gyn. Brit. Empire, May, 1903.

IT is stated that there were 702,083 paupers in England and Wales at the end of May, London alone claiming 105,277 of these. The ratio is 21.3 per 1,000 of the population, as against a proportion of 48.3 per 1,000 in 1863.

Reports of Societies.

THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

TWELFTH ANNUAL MEETING, HELD IN BOSTON, MAY 19, 20 AND 21, 1903.

THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES opened its twelfth annual meeting in Faneuil Hall, Boston, Mass., where addresses of welcome were made by the Hon. J. L. Bates, Governor of the Commonwealth, Dr. George E. Francis of the Massachusetts Medical Society and Surgeon-Gen. Robert A. Blood of the governor's staff. General Blood discussed the value of the Association of Military Surgeons in bringing into harmony the work of the medical officers of the Regular Service, the National Guard and the Volunteers, considering this in the light of his own practical experience during the War of the Rebellion and the Spanish-American conflict, and held that with the facilities afforded by the association for uniform conduct nothing but the failure of the government to make prompt, proper and ample appropriations could interfere with the highest efficiency of the medical service.

PUBLIC SERVICE MEDICAL SCHOOL.

LIEUT.-COL. J. V. R. HOFF, U. S. A., as chairman of the committee upon this subject, reported briefly on the work of the army and navy medical schools for the year, and described the recommendations of the surgeon-general of the army relative to the establismhent of an army medical school in which a candidate, a medical graduate, should pass one year as a medical cadet and four years as a medical officer, during which period he should bind himself not to marry without permission from the Secretary of War. Colonel Hoff, however, proposes to go still farther and educate the government medical officers *ab initio* at an institution similar to the military academy at West Point, in which preparation shall be made for all branches of the medico-military service, and presented numerous cogent arguments in favor of the plan.

COL. R. R. DE WREDEN, Russia, described the Imperial Medical School at St. Petersburg, in which he was on duty. This school gives its students their entire medical as well as military education, and its graduates are assigned to hospitals or to regiments in accordance with their class standing; the seven highest are sent abroad to elaborate their studies and return as adjunct professors, the next highest men are assigned to hospitals and the remainder to regiments.

THE EDUCATION OF THE MEDICAL OFFICER OF THE ARMY.

MAJOR W. C. BORDEN, U. S. A., gave a succinct survey of the subject of postgraduate instruction in the United States army, especially dwelling upon the work of the army medical school, and incidentally referring to the similar schools of other countries. He believed in the extension of the facilities of the army medical school to the medical officers of the militia.

SURGEON H. G. BEYER, U. S. N., would limit the work of the school to distinctly military medical study.

COL. G. S. RYERSON, Canada, appreciated particularly the necessity of training the medical officer in the administrative features of his duty, and described the Canadian method of attaining that end.

COL. W. J. CHARLTON, England, described the preparation of the young medical officer in the British service, beginning formerly at Netley and finishing at Aldershot. Since the Boer War the Netley School has been supplanted by the Royal Medical Staff College in London. He noted also that postgraduate work had been established for all officers up to the grade of lientenant-colonel by detail at large London hospitals.

MEDICAL INSPECTOR J. C. WISE, U. S. N., dwelt upon the fact that a military medical officer is first of all a doctor, and urged that this fact be not lost sight of in technical training.

MAJOR W. C. BORDEN, U. S. A., admitted the necessity of thorough professional training in the military medical officer as a prime factor, but he recognized that in military service administrative work was also of great importance. The former the militia and volunteer officer had ample opportunities to acquire; it was not proposed to extend to him the opportunity of obtaining the latter also.

MAJOR AZEL AMES, U. S. V., did not deny the value of training in administrative work, but he feared that it would not be practicable to secure a considerable attendance of militia officers at a national military medical school.

LIEUT.-COL. C. C. FOSTER, Massachusetts, suggested the preparation of a published guide to the militia medical officer, and dwelt upon the value which such a work would have had in his own work in the Spanish War.

GEN. E. C. BRUSH, Ohio, remarked that in Ohio medical officers were appointed for life, and believed that if there were a military medical school at Washington adapted to their instruction, his young officers would attend it.

LIEUT.-COL. N. S. JARVIS, New York, commented upon the professional absorption of the young practitioners from whom the junior medical officers of the National Guard were to be drawn, and the difficulty with which they could get away to a military medical school.

MAJOR G. C. JONES, Canada, adverted to the evolution of the Canadian Army Medical Staff, during which the government sent a number of medical officers to England in order that they might become instructors of their comrades, which was done in the annual camps of instruction. He described his experience with the Canadian contingent in the Boer War, and referred to the need also of instruction by the non-commissioned officers of the medical department.

LIEUT.-COL. J. K. WEAVER, Pennsylvania, doubted the practicability of educating militia medical officers at a national school, and was favorably impressed with the idea of placing in the hands of medical officers such literature as may be necessary for their information.

THE ACTING ASSISTANT SURGEON.

MAJOR AZEL AMES, U. S. V., commented upon the anomalous position of the acting assistant or contract surgeon of the army, observing that he had all the responsibilities and shared all the dangers of his commissioned confrère without either the honors or rewards to which the latter may look forward. He can anticipate no promotion, he has no increase in pay for length of service, he has no retirement nor pension when he becomes worn out in the service. The author forcibly urged the improvement of the status of the civilian military surgeon in every respect.

THE DEGREE OF DOCTOR OF PUBLIC HEALTH.

MEDICAL DIRECTOR PAUL FITZSIMONS, U. S. N., emphasized the necessity for expert sanitary training for military and naval medical officers, and showing that their training and experience makes them *de facto* if not *de jure* doctors of public health.

THE UNITED STATES ARMY GENERAL HOSPITAL AT THE PRESIDIO OF SAN FRANCISCO, CAL., 1901–1902.

COL. ALFRED C. GIRARD, U. S. A., made an exhaustive report of one of the largest of the United States army hospitals during its most active period, which was divided into six parts: (1) General Administration, (2) Medical Work, (3) Surgical Work, (4) Bacteriological Work, (5) Eye, Ear, Nose and Throat Work and (6) X-ray Work. The enlisted force on duty averaged five hospital stewards, nine acting hospital stewards and one hundred and sixty-seven privates. During the year five hundred and six female nurses were on duty, the average per month forty-one. The total number of patients was four thousand five hundred and fifty-one, with ninety-two deaths. The surgical cases of the year numbered seven hundred and twenty-eight, of which one hundred and six were herniotomy, thirty-five were for varicocele, twenty-seven for appendicitis, fifty-eight for gunshot wounds, ten for bolo wounds, ten for hepatic abscess and twenty-seven for tumors. The paper followed with a concise description of the methods of operating employed in connection with hemorrhoids, appendicitis, hernia and varicocele. The pathological and bacteriological work of the hospital was of a specially high order and in charge of Dr. C. F. Craig. The blood and urine of every patient was examined in all cases of suspected pulmonary tuberculosis or diarrheal trouble, and the report included a valuable study of the results of his work, throwing much light upon malarial, estivo-autumnal and Malta fever and dysentery. The report was accompanied by particularly valuable appendixes upon liver abscess and the mosquitoes of the Philippines.

AMBULANCE FOR MOUNTED TROOPS.

The author, LIEUT.-COL. H. G. HATHAWAY, R. A. M. C., was medical officer in charge of Cavalry Divisional Staff during the South African War and was greatly impressed with the difficulty of keeping the medical department in touch with the rapidly moving forces with which he was on duty. He endeavored to accomplish this in two ways: (1) By an appliance to be attached to the saddle for the use of men who were able to remain mounted with a suitable support. This saddle support consists of an encircling padded belt connected with the saddle by a metal leather-covered support behind. (2) By a light, strong platform cart with strong springs so arranged as to carry eight sitting or two recumbent cases. These appliances were carefully described and the equipment detailed with care.

QUARANTINES AS THE PICKET-LINE.

SURGEON P. C. KALLOCH, P.H. and M.H.S., gave an eloquent description of the work, privations and accomplishments of the quarantine officer.

THE SURGEON-GENERALS OF THE ARMY.

MAJOR JAMES EVELYN PILCHER, U. S. V., read a series of biographical sketches of the chiefs of the medical department of the army, from the Revolution to the close of the hostilities in the Philippines, illustrated by a complete series of portraits, many of them displayed for the first time.

NEW ENGLAND MEN IN THE MEDICAL CORPS OF THE NAVY OF THE UNITED STATES.

MEDICAL INSPECTOR F. B. STEPHENSON, U.S.N., presented a comprehensive historical sketch of the Navy Medical Corps, with a list of the natives of New England who had served as naval surgeons, and biographical sketches particularly full in relation to representatives from the Commonwealth of Massachusetts.

THE INSTRUCTION OF THE HOSPITAL CORPS IN COMPANIES AND DETACHMENTS.

The author, CAPT. F. P. REYNOLDS, U. S. A., had been in command of the U. S. Army Hospital Corp, Company of Instruction No. 1, for several years, and spoke with recognized authority on his subject. The points noted were: (1) Methods of maintaining discipline, (2) bearer drill, (3) anatomy and physiology, (4) diet cooking, (5) nursing, (6) care of animals, (7) first aid, (8) field work, (9) clerical work, (10) materia medica and pharmacy. The principles upon which the company work should be based appear to be: (1) To at once impart a thorough knowledge of discipline in the same way and by much the same methods as it is imparted in the line of the army, with which the hospital corps is always serving. (2) To teach men the principles

of order and neatness, both as regards themselves and their personal equipment, and also to familiarize them with the departments of a hospital and the articles with which they work. (3) After this, to impart to each man a knowledge, as far as his mental capacity will permit, of practical nursing, of preparation of diets for the sick, of first aid and transportation of the wounded, and of ambulance driving and care of animals. (4) To teach them to care for themselves and the equipment entrusted to them in field service, and to be familiar with the usual duties of hospital corps men on the march, in camp and during an engagement. (5) To instruct in clerical work, materia medica and pharmacy, those who have aptitude for such work.

SICK-BAY NOTES.

SURGEON G. F. STOKES, U. S. N., read a selection of a few cases from the medical journal of the steamship *Oregon* to show the varied character of naval practice, and comprised: (1) Pneumonia, (2) fracture of the base of the skull, (3) varioloid, (4) typhoid, (5) filaria sanguinis hominis, (6) malarial fever, (7) tuberculosis, (8) fracture of the tibia, (9) diphtheria.

SERVICE CONDITIONS IN RELATION TO RETIREMENT AND PENSIONS.

MEDICAL DIRECTOR JOHN C. WISE, U. S. N., stated that the medical officers of the army and navy are more directly responsible than any one else for the ultimate incidence of our vast pension appropriation. The author urged the highest care in diagnosis and record, with especial attention to the question of incurrence in the line of duty.

CIRCUMCISION AND FLAGELLATION AMONG THE FILIPINOS.

LIEUT. C. N. BARNEY, U. S. A., commented upon the prevalence of circumcision among the Philippine indios. A polished piece of wood, sufficiently curved, is driven into the ground so that the boy to be operated upon can squat upon his hands and insert the free end of the stick, which is pointed, between the glans penis and the prepuce; after the prepuce has been drawn over the point, the operator places a knife so that the edge rests lengthwise upon it and gives the blade a sharp blow with a stick, thus dividing the tissues and exposing the glans. The wound is dressed with guava leaves in poultice or in powder. The results of flagellation were also described and their treatment commented upon.

PREVENTION OF THE SPREAD OF INFECTIOUS DISEASES ON BOARD SHIP.

SURGEON HENRY G. BEYER, U. S. N., in reading this paper confined himself to the consideration of measles, an affection of singular importance in military and naval service, and recognized that the chief danger of infection in this and allied diseases lay first and foremost with the patient himself and only secondly with persons and things with which he had been brought into contact. The author's practice then was, having diagnosed the disease, to spread out a clean white sheet upon which the patient stepped and left all his clothes including his shoes; all were sterilized by steam except the shoes, which were disinfected with a solution of bichloride of mercury. The patient received first a thorough scrubbing with soap and warm water and a complete sponging with bichloride (1:2000), and was put to bed wrapped in a sheet moistened with the same solution. The bichloride bath was repeated three times daily during the height of the eruption, twice a day thereafter. The mouth and nose were cleansed frequently with normal salt solution containing a minute quantity of carbolic acid or bichloride. Antiseptic cloths were provided for the secretions of coughing or sneezing. All excretions were immediately disinfected and all complications promptly treated. While the patient was in bed all his clothing was disinfected. By use of these precautions it was possible to readily control the spread of the affection.

THE PRESERVATION OF THE HEALTH OF THE SOLDIER.

BRIGADE-SURGEON LIEUT.-COL. WILLIAM HILL-CLIMO, A. M. S., concluded after an interesting survey of the subject, both from British and American standpoints, that a nation whose system of recruitment is voluntary should use every effort to improve the physical development of the people, so that all classes in an emergency should be equally capable of undertaking military service; that, after enlistment, the recruit should be prepared for training which he should not undergo until pronounced fit; that during training, and all through his subsequent service, his health should be carefully supervised; that these measures are specially required for countries whose army organization is not single but composite, that is to say, when the troops consist of regulars, militia, volunteers, etc., and are raised under different conditions of service; that these measures must be entrusted to the medical service, and that full power must be given it to carry them out.

THE RESULTS OF TWO SEASONS OF ANTI-MALARIA WORK.

LIEUT. F. F. RUSSELL, U. S. A., summarized in this paper the observations made at Fort Washington, Md., on the left bank of the Potomac, thirteen miles below Washington. The use of petroleum upon the stagnant breeding pools in the neighborhood was immediately beneficial, resulting in the first year in the diminution of the percentage of malarial cases from 19.53% to 8.63%, which was still farther reduced the following year to 4.18%. The oiling was soon regarded as merely a temporary resort, and a general drainage system was provided. He notes also the great increase in the comfort

of living due to the abolition of great swarms of culex, which formerly made life almost unendurable.

EPIDEMIC CATARRH ON SHIPBOARD.

PASSED ASSISTANT SURGEON DUDLEY N. CARPENTER, U. S. N., related a year's clinical observation on the battleship *Illinois*. Especial attention was directed to the evils of poor ventilation and overcrowding in accentuating the disease, while the etiology, clinical history and treatment were fully considered

TREATMENT OF TUBERCULOSIS AT FORT STANTON, N. M.

SURGEON PAUL M. CARRINGTON, P. H. and M. H. S., spoke of the climate as characterized by extreme dryness, a large proportion of sunny days and great purity of the atmosphere, which appears to be free from pathogenic germs, — wounds of all kinds healing very kindly and without infection even with the most careless disregard of asepsis. On the appearance of winter, mixed infection cases invariably lose their mixed character. The rarefaction of the atmosphere makes deeper breathing necessary and the decreased barometric pressure induces a diminished liability to hemorrhages. The author is a sturdy advocate of tent dwelling for the consumptive. The spread of infection is controlled by the use of the spit-cups and periodical disinfection of apartments. While an advocate of exercise under favorable conditions, the author believes that the advice to "go West and rough it on a ranch" is responsible for many unnecessary deaths.

THE MEDICAL TREATMENT OF APPENDICITIS IN ACCORDANCE WITH THE MODERN PRINCIPLES OF THERAPEUTICS.

LIEUT. E. CASTELLI, the Italian delegate, believed the disease to be a closed wound in which the colonization of microbes and the action of toxins accomplished their work undisturbed. The therapeutic equation to be solved is the same as that reached by surgery, except that for the term "local antisepsis" must be substituted the term "general antisepsis," and internal antisepsis becomes the basis of action. The appendix must be considered as a tubular ganglion receiving germs either from the blood or the lymphatics, whence appendicitis may become a complication in cases of scarlet fever, pneumonia, erysipelas, parotitis, etc. The author is profoundly opposed to the internal treatment by opium or the local action of ice, but resorts to preliminary treatment by salicylate of sodium as a cholagogue and anti-thermic; three hours later he begins to administer calomel for its action as an intestinal antiseptic, cholagogue, laxative diuretic and stimulant of the pancreatic secretions. For the relief of pain he employs the warm bath and enemata of hot salt solution. The bacterial cause of the trouble, residing in the blood, is treated by subcutaneous injection of a dilute solution of carbolic acid.

THE PATHOLOGY OF LATENT MALARIAL INFECTION AS OBSERVED AT AUTOPSY.

LIEUT. CHARLES F. CRAIG, U. S. A., by latent infection means malarial infection, which is not manifested by any symptoms and in which an examination of the blood does not necessarily show the presence of malarial parasites. The pathology of latent tertian infection is confined almost entirely to the spleen, the liver being but slightly involved. The changes in the spleen consist chiefly in an engorgement of the splenic sinuses with red cells and leucocytes, the presence of infected red cells and of phagocytes and melaniferous leucocytes, an increase in the cells of the splenic pulp with more or less degeneration and karyokinesis and pigmentation of the organ confined to the edges of the Malpighian corpuscles and the splenic sinuses and trabeculæ. In the liver the chief changes consist in slight pigmentation, more or less venous congestion and the presence of melaniferous leucocytes. The pathology of latent estivo-autumnal infection is also confined practically to the spleen, and it is observed that the parasite is capable of undergoing its entire human life cycle within the spleen, and in such numbers as not to be found in the peripheral blood upon repeated examinations. These facts go to bear out the time-honored theory that the spleen is the seat of malarial infection.

HYSTERIA IN THE MALE.

SURGEON S. G. EVANS, U. S. N., invited attention to the frequency of hysteria in the male in naval practice, and detailed an unusual case of the affection.

AN EPIDEMIC OF DIPHTHERIA ON SHIPBOARD.

MEDICAL INSPECTOR G. E. H. HARMON, U. S. N., gave a careful study of an epidemic diphtheria which occurred upon the United States training ship *Buffalo*, and was particularly noteworthy because of the large number of cases among male patients in early manhood otherwise in robust health, not a case being contracted by a person above the age of thirty. Eighteen percent of the ship's company of 750 men suffered from the disease, and of the 137 cases not a single death occurred after antitoxin treatment was begun. Great care was taken in the examination of the entire ship's company, and all those who showed the presence of the Klebs-Loeffler bacterium were immediately subjected to treatment. The disinfection of the ship and the crew was described with great care.

MAJOR FREDERICK SMITH, D.S.O., R.A.M.C., read a paper on

THE DIFFERENTIAL DIAGNOSIS OF TYPHOID FEVER IN ITS EARLIEST STAGES.

This was the Enno Sander prize essay, and the fact of its award to an officer of the military service of another country was greeted with hearty applause. Major Smith's essay was divided into thirteen chapters: (1) Introduc-

tory. (2) Subjective early symptoms illustrated by the author's personal experience. (3) Objective symptoms. (4) Temperature as an aid to diagnosis of typhoid. (5) Typhus and relapsing fevers. (6) Tuberculosis, diseases of the respiratory system and influenza. (7) Meningitis, septicemia, puerperal fever, pyemia, endocarditis, pericarditis, glanders. (8) Gastro-enteritis, inflammation in the neighborhood of the cecum, dysentery. (9) Febricula, or simple continued fever. (10) Malta fever. (11) Malarial fever. (12) Plague and other diseases which have been mistaken for typhoid. (13) Chemical reactions and microscopical methods in relation to the earliest stages of typhoid. He concluded that in the field the medical officer must rely mainly upon his clinical acumen, and summarized his studies in that direction as: (*a*) There is scarcely any disease accompanied by fever which has not been at times mistaken for typhoid fever. (*b*) A good many cases are wrongly diagnosed owing to mere carelessness or to want of knowledge. (*c*) The disorders most liable to be confounded with typhoid fever are: typhus fever, tuberculosis, pneumonia, influenza, febricula or unnamed continued fever, Malta fever, malarial fever and paratyphoid. (*d*) It is frequently impossible by non-bacteriological methods to differentiate between typhoid and the diseases named above in four days or even a week and more. (*e*) Our safety from a public health point of view lies in regarding all doubtful cases as typhoid until they have been proved to be something else. (*f*) The anomalous cases are more numerous and the difficulties in the way of diagnosis greater in military than in civil life.

In his last chapter he discussed the diazo reaction and fecal, sputum and blood examinations, which, however, he considered hardly practicable in the field, although the serum test is the most reliable and generally practicable of these.

The second place in the prize competition was awarded to ASSISTANT SURGEON W. C. RUCKER, P. H. and M. H. S., whose paper may be epitomized as follows:

(1) There is no single symptom on which alone an early diagnosis of typhoid fever can be made. It is only by careful consideration of the symptom-complex that a clinical diagnosis can be arrived at. (2) The most trustworthy, as well as the earliest, sign of typhoid fever is the presence in the circulating blood of the bacillus of Eberth. (3) The demonstration of the bacillus of Eberth is found in the feces later than in the blood, but with comparative ease. The presence of the B. typhosis in the feces is of great value as a corroborative sign. (4) The presence of the bacillus typhosis in the rose spots is a trustworthy sign, but has no advantages over the examination of the blood from other localities. (5) The serum reaction of Widal is seldom demonstrable during the earliest stages of typhoid fever. It is of value only in the higher dilutions.

HISTORY, CAUSE AND MODE OF TRANSMISSION OF YELLOW FEVER, AND THE OCCURRENCE OF SIMILAR TYPES OF FATAL FEVERS IN PLACES WHERE YELLOW FEVER IS NOT KNOWN TO HAVE EXISTED.

LIEUT. JAMES CARROLL, U. S. A., read an encyclopedic paper tracing the yellow fever from its earliest history to the present time, beginning with the Barbadian epidemic of 1647 and closing with the decline of the disease in Cuba last year. The author was himself the subject of the first experimental case of inoculation with yellow fever by the stegomyia fasciata, and from this and numerous other experiments, reinforced by an exhaustive study of the subject in all its bearings, he concludes that yellow fever as we meet with it is contracted only through the bite of an infected mosquito twelve days or more after feeding upon a patient in the early period of the disease. Experimentally the disease can be produced by the subcutaneous injection of blood or even the unfiltered blood serum of a patient, provided the material can be obtained sufficiently early in the attack.

TREATMENT OF YELLOW FEVER AT LAS ANIMAS HOSPITAL IN HAVANA.

The author, COL. W. C. GORGAS, U. S. A., emphasized the desirability of receiving the patient during the first three days of the attack, and of maintaining him in a recumbent position absolutely without exertion. During the active stage, food was prohibited, and milk began when the temperature subsided unless contra-indicated. Water and cracked ice was permitted *ad libitum*. Cathartics were employed as needed and phenacetine for headache or muscular pains. For urinary suppression or diminution saline enemata and local applications to the back were given. The convulsions were not so largely uremic as had been supposed, but were generally due to the yellow fever poison itself. Gastric hemorrhage is best treated by cracked ice and rest, without astringents. The drugging employed by the Spanish physicians is not approved of, and this view is endorsed by the lower mortality of the American hospital, in which twelve lives more per hundred were saved than in the most successful of the native institutions.

SOME OBSERVATIONS MADE IN THE PHILIPPINES.

SURGEON J. A. GUTHRIE, U. S. N., opened with a humorous picture of the germophobist of the Philippines, the author in happy vein calling attention to some important points to be observed by those going to our possessions in the Southern Seas. Of prime importance is attention to the skin both from a hygienic and entomologic standpoint. He notes the remarkable effect of a land leech in breaking soldiers down on a march. The liquor called "tuba," he describes as a fermented solution of more or less poison-

ous insects, while "bino" is another most dangerous alcoholic poison. Repression of energy, and rest during the heat of the day, are essential to physical welfare, and the American must give up and return home upon the first accession of tropical disease if he desires to save his life. The prevalence of the ever-present dhobie itch is commented upon and precautions against it detailed, while the use of frequent antiseptic washes, douches and gargles is advised.

SANITARY CONDITION OF THE TOWN OF SURIGAO, MINDANAO.

CAPT. HENRY DUR. PHELAN, U. S. V., submitted a report to the chief surgeon of the Philippines, by whom it was forwarded to the surgeon-general of the army, with the recommendation that it be laid before the association as a minute and accurate description of life in a Philippine village, with especial reference to the conditions requiring sanitary attention. It was accompanied by numerous photographs, and comprised a panoramic view of one of the most important phases of the work of the military medical officer in our island possessions.

NOTES FROM THE EXPERIENCES OF A MEDICAL OFFICER IN THE TROPICS.

MAJOR C. F. MASON, U. S. A., employed the term "Diseases in the Tropics" instead of "Tropical Diseases," because there are few if any diseases which occur only in the tropics, but diseases are modified by their occurrence in the tropics, and the relative prevalence of particular diseases is very different from that obtaining in temperate climates. He makes an interesting comparison of the relative frequency of certain diseases in Porto Rico and Panay — filariasis and ankylostomiasis being rare or absent in Panay, while beri-beri and certain fevers are rare or absent in Porto Rico. Gastro-intestinal disorders, especially diarrhea and dysentery, loom up as of overshadowing importance among diseases in the tropics, but he believes that a large percentage of these cases are preventable by the exercise of suitable hygienic precautions.

MALARIAL SCIATICA.

PASSED ASSISTANT SURGEON E. O. HUNTINGTON, U. S. N., read this paper. In view of the increased prominence given to malarial affections by the extension of tropical service, the author submitted a case of extreme sciatica, in which the presence of the quartan parasite was clearly demonstrated and in which recovery was secured by the exhibition of quinine in full doses both by the mouth and by injection directly into the sheath of the nerve.

SOME OBSERVATIONS ON FRACTURES OF THE SKULL.

CAPT. ROBERT E. BELL, M. V. M., read this paper, which was a valuable clinical study of cranial fractures, based upon extensive personal experience by the author.

SPINAL ANESTHESIA IN MILITARY SURGERY.

The delegate from the Mexican Army LIEUT.-COL. AUGUSTIN AGUIRRE, presented an interesting report upon the subarachnoid injection of hydrochloride of cocaine according to the method of Tuffier as practiced at the Mexican Military Hospital of Instruction. Colonel Aguirre makes an injection exactly in the middle line below the spinal apophysis of the third or fourth lumbar vertebra, or possibly below the second or first, in which case the needle passes perpendicularly through the skin, cellular tissues and ligaments at the widest portion of the intervertebral space. To obviate clogging of the needle it is provided with a mandril to be removed when the canal is penetrated. Care is taken to have the solution completely sterilized, to allow the exit of an amount of cerebro-spinal fluid equal to the amount of the solution injected, and to have the patient maintain a sitting posture so as to permit the cocaine to remain in the lower portion of the spinal canal. The advantages of the method are: (1) Ease of application; (2) the possibility of its being performed by the surgeon himself; (3) speedy action — ten minutes as a rule; (4) absolute safety; and (5) a small arsenal, easily carried and readily sterilized. The paper was accompanied by a report of two hundred and ten cases in which the method had been employed.

AN EXTERNAL SUTURE.

CAPT. THOMAS PAGE GRANT, Kentucky, spoke of an application consisting of strips of adhesive plaster with hooks on one end to be attached on either side of the wound, which are drawn together by rubber bands. The application was practically demonstrated upon the living subject.

MY FIRST AID TO THE WOUNDED.

LIEUT.-COL. HENRY O. MARCY, U. S. V., read an interesting description of the trip of the steamer *S. R. Spaulding*, transporting the wounded from City Point, Va., to Philadelphia after the seven days' battles, in 1862. The sufferings of the wounded due to insufficient surgical treatment were clearly brought out, the ultimate results of better care were shown and the methods applied to this end described.

TROPICAL ABSCESS OF THE LIVER.

LIEUT. E. W. PINKHAM, late U. S. A., gave a report of sixteen cases of hepatic abscess occurring in the Military Hospital at Iloilo, Panay, from Aug. 5, 1900, to April 20, 1901, with operation and results. Of the sixteen cases there were seven recoveries, and the author attributes the high mortality to the failure to recognize the trouble at a sufficiently early period. He observes that the so-called abscesses of the liver are not abscesses nor are their contents pus; they are rather areas of necrosis or liquefaction of the liver tissues, and made up of liver cells in all stages of degeneration and disintegra-

tion, free fat globules, more or less of blood corpuscles and serum. He comments upon the freedom with which the liver may be examined without dangerous hemorrhage, and objects strongly to evacuation and drainage by means of the trocar and canula, urging free incision.

WOUNDS BY LEAD AND JACKETED BULLETS IN THE CUBAN INSURGENT WAR.

CAPT. E. C. POEY, U. S. V., was a brigade surgeon in the Cuban army, and afterwards a medical officer of the United States army in Cuba, the United States and the Philippines. He remarks that a ricochet shot is more injurious than a straight shot, and believes that in any shot wound the less surgical interference the better. The Mauser bullet is the most humane and the Krag is the next; the stopping power of both is *nil*. He has observed a number of cases of spontaneous recovery from abdominal wounds with small caliber bullets, and is an advocate of non-intervention in these as well as other cases.

DISLOCATION OF THE FIRST METATARSAL BONE.

SURGEON HENRY W. SAWTELLE, P. H. and M. H. S., reported a case of direct dislocation of the proximal end downwards and outwards into the plantar arch with a forcing upward and inward of the internal cuneiform. Reduction by manipulation having failed, an incision was made and replacement effected by direct force.

EARLY RADICAL TREATMENT IN ADENITIS INGUINALIS.

ASSISTANT SURGEON R. L. SUTTON, U. S. N., advocated prompt extirpation by the knife as a means of expediting recovery from inguinal adenitis, often so prolonged and intractable a cause of absence from a soldier's or sailor's duty. He gave a table of ten cases showing the rapid result of the treatment.

TREATMENT OF ANTERIOR DISLOCATION OF THE SHOULDER.

ASSISTANT SURGEON-GEN. G. TULLY VAUGHAN, P. H. and M. H. S., recommended the following methods in the order given: (1) Direct reposition. (2) Extension and counter-extension. (3) Kocher's method. (4) Arthrotomy — and related a case in which all were successively employed, free opening finally showing that reduction had been provided by a detached greater tuberosity; reduction was then easily effected by pressure in the axilla with adduction of the arm.

SUBDURAL HEMORRHAGE WITHOUT FRACTURE.

SURGEON F. W. F. WIEBER, U. S. N., reported a case of football injury in a midshipman at the Naval Academy. Intracranial clot and irritation over the motor area on the left side of the brain was diagnosed, and the brain exposed at the point located, verifying the diagnosis. The clot was removed, and the patient made a rapid and complete recovery. The operation was indicated because: (1) the epileptic symptoms were on the increase; (2) it was feared that the respiratory muscles would become seriously involved; and (3) absorption of the clot might have been imperfect and permanent epilepsy might have become established.

THE INTEROCEANIC CANAL.

The following resolutions were presented by LIEUT.-COL. J. K. WEAVER, Pennsylvania, and unanimously adopted:

Whereas, It is well known that the previous excavations for an isthmian canal have been attended with a large amount of illness and a heavy mortality due mainly to malaria and yellow fever, and

Whereas, Recent discoveries as to the cause of these diseases have enabled medical officers to control their ravages to a marked degree, and

Whereas, The success which has crowned medical efforts in Cuba in abolishing yellow fever in the island, almost banishing malaria from Havana and entirely eradicating malaria as a factor of the death-rate of the army in Cuba, is conclusive evidence that, if proper hygienic precautions are taken at Panama and other situations along the route of the projected interoceanic canal, the death-rate of the past can be diminished and practically made to disappear; therefore be it

Resolved, That in the judgment of the Association of Military Surgeons of the United States, in annual meeting assembled, the amplest power should be given to the medical officers in charge of the sanitation of the canal, and that, to attain this end, the medical officer in charge should be a member of the commission which the President of the United States is authorized to appoint to conduct the affairs of the canal; and be it further

Resolved, That the secretary of the association is instructed to forward this preamble and resolutions, properly attested, to the President of the United States.

THE INTERNATIONAL MEDICAL CONGRESS.

GEN. J. D. GRIFFITH, N. G., Missouri, made an interesting report on the International Medical Congress at Madrid, at which he was an accredited delegate from the association.

INCORPORATION BY CONGRESS.

The Committee on Incorporation announced, through its chairman, MAJOR W. C. BORDEN, U. S. A., that the association was incorporated by Act of Congress approved Jan. 30, 1903, and the association then proceeded to reorganize under the law. The act, among other things, officially recognized the insignia of the association and authorized it to be worn with the uniform.

OFFICERS AND PLACE OF MEETING FOR 1904.

The following were elected officers for the ensuing year: President, MEDICAL DIRECTOR JOHN C. WISE, of the United States Navy; First Vice-President, SURGEON-GENERAL WALTER WYMAN of the United States Public Health and Marine Hospital Service; Second Vice-President, MAJOR ALBERT H. BRIGGS of New York; Third Vice-President, GEN. ROBERT M. O'REILLY of the United States Army; Secretary and Editor, MAJOR JAMES EVELYN PILCHER of the army; Treasurer, MAJOR HERBERT A. ARNOLD, Pennsylvania. St. Louis was selected as the place of meeting for 1904, provided that suitable accommodations can be furnished.

Recent Literature.

Disease of the Pancreas: Its Cause and Nature. By EUGENE L. OPIE, M.D., Associate in Pathology in the Johns Hopkins University, Fellow of the Rockefeller Institute of Medical Research. Philadelphia and London: J. B. Lippincott Company. 1903.

In the list of names of those identified with the study of the pathology of the pancreas a conspicuous place is occupied by that of Opie, and the volume now under consideration gives ample evidence of the breadth and thoroughness of his work. The studies of the anatomy of the pancreas are noteworthy, since they include the results of the dissection of one hundred specimens with reference to the number and course of the ducts and to the presence of accessory pancreatic tissue. The importance of this inquiry is apparent when it is recognized that conclusions from experiments on the pancreas must be controlled by evidence that in the experiments concerned attention was directed to the possibility of accessory ducts and of detached foci of pancreatic tissue.

Opie's investigations with regard to the function and lesions of the islands of Langerhans make his assertion almost conclusive when he states that considerably more than one half of all cases of diabetes are due to injury of these islands.

The title of the book sufficiently indicates its scope. Without being a comprehensive treatise on diseases of the pancreas, it includes the consideration of some of the most important affections of this organ. It shows how they arise, what are the resulting disturbances, and gives evidence of value in their diagnosis, prognosis and treatment. The volume is of value to every student of pancreatic disease and will interest both physician and surgeon. It is gratifying to learn that the Rockefeller Institute of Medical Research aided the completion of the work.

A Textbook of Histology and Microscopic Anatomy of the Human Body, including Microscopic Technique. By DR. LADISLAUS SZYMONOWICZ. Translated and edited by JOHN BRUCE MACCALLUM. Illustrated with 277 engravings, including 57 plates in colors and monochrome. 8vo, pp. 435. Philadelphia: Lea Brothers. 1902.

In default of American textbooks of histology, we have come to rely mainly upon translations of German manuals of the science, two of which have already won general recognition for themselves. The new candidate for favor is really the most condensed and briefest work we have had, although it forms a bulky and heavy volume, being in large type and printed on heavy paper, so that it appears more than twice the size of Schäfer's "Essentials of Histology," although containing much less matter. It has two special merits — one the excellence of the illustrations, which have for the most part been specially prepared for the work, the other the incorporation of many of the results of researches carried on in Professor Mall's laboratory in Baltimore, researches which have failed to receive the recognition they deserve. Very scant attention is given to other American work. Neither the author nor the editor shows a thorough mastery of the subject, although both have a sound knowledge of histology, so that while they have produced a textbook which will prove acceptable to students, they have not produced an authoritative manual of reference for advanced workers, because they have left many recent investigations unheeded,— such as those on the vitreous body, of Mingazzini on the intestinal epithelium, those on the circulation of the liver, on the structure of the placenta, etc. Students will appreciate the clear statement of the facts by the author and the idiomatic excellence of the translation by the editor, and we must all admire especially the beauty of the colored illustrations, which have been wisely chosen to show features less well to be demonstrated by mere black and white figures. The closing chapter on technique seems to the reviewer unsatisfactory. There is a good index.

The Medical and Surgical Uses of Electricity. By A. D. ROCKWELL, A.M., M.D. New [tenth] edition. 8vo, pp. xvi, 656, with two hundred and fifty-two illustrations. New York: E. B. Treat & Co. 1903.

In this new edition of a well-known book, chapters have been added on the x-ray, the Finsen light, vibratory therapeutics and high-frequency currents, and other chapters have been revised. The revision, however, is merely an example of putting new cloth into a very old garment which has outlived its usefulness.

Mechanical Vibratory Stimulation. Its Theory and Application in the Treatment of Disease. By MAURICE F. PILGRIM, M.D., First Vice-President of the American Electro-Therapeutic Association, etc. New York: The Lawrence Press.

The aim of the author in this small book of 152 pages is to indicate the therapeutic value of mechanical vibration, to establish a rational basis for this type of treatment and to make the method available to the practitioner. The result is a carefully written and well-illustrated book, which should at least call attention to this little-practiced form of treatment.

THE SPITTING NUISANCE IN PHILADELPHIA. — A vigorous attempt is being made in Philadelphia to abate the spitting nuisance, through frequent arrests. A few public examples should do much toward the abatement of this widespread habit. The mere exhibition of prohibition notices has been proved to be of small avail.

THE BOSTON

Medical and Surgical Journal

THURSDAY, AUGUST 13, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SPOTTED FEVER.

WE have previously alluded somewhat briefly to the work which has been done in the study of so-called spotted fever of the Rocky Mountains. The general importance of the subject, and the very great interest attaching to disease transmitted as this appears to be, justify a somewhat more extended statement of the course of the work and the preliminary conclusions which those engaged in it have reached. The detailed account of the work appears in the first biennial report of the Montana State Board of Health. It is worthy of note that so unusual a piece of investigation should have inaugurated the publication of this report. As is perhaps generally known, the work of investigating the disease has fallen to the lot of Dr. Louis B. Wilson and Dr. William M. Chowning, both connected with the Minnesota State University in the capacity of pathologists.

Soon after the organization of the State Board of Health of Montana, the desirability of investigating a peculiar localized disease of the Bitter Root Valley, known in that locality as spotted fever, became apparent. The supposed causes — water, conditions of the soil, snow from the Bitter Root Mountains and various local conditions — were soon proved insufficient to explain the incidence of the disease. In view of the fatality of the affection, its curious localization in a particular valley, and the general interest attaching to an apparently new disease, the physicians we have mentioned were chosen systematically to prosecute the research. The investigation has now been in progress upwards of a year, and certain conclusions, although acknowledged to be preliminary, seem to be of much practical and theoretical importance.

It was found that the first case of spotted fever in the Bitter Root Valley occurred in 1873, when there were but few white men resident there. It apparently had not occurred among the Indians, who continued to inhabit the valley until 1890. Since its appearance about two hundred cases of the severer form of the disease have occurred, with a mortality of 70 to 80%. Through the co-operation of the physicians of Western Montana a table has been drawn up including 114 cases, with a more or less complete clinical history, showing the important points connected with the course and outcome of the affection. It has been found that the disease is confined to the Bitter Root Valley in an area from four to ten miles by fifty miles long. It is doubtful whether any cases have originated outside of this territory, excepting eight in a small valley twenty miles east of the Bitter Root Valley. The practical limitation of cases to the west side of the valley is also strikingly shown by the investigations. The population of the valley is largely made up of ranchers, who are, as a rule, cleanly in habits and healthy. The greatest number of cases have occurred in May and June, and but little importance can be attached to the general health of the patient in determining his susceptibility to the disease. Age apparently, apart from other considerations, plays little part in predisposing to the disease. The onset of the affection is characterized by elevation of temperature, a generalized eruption beginning on the abdomen and gradually extending to other parts of the body, hence the name "spotted fever." In general, in the more serious cases, the disease runs the course of a highly acute infection with cutaneous manifestations.

During their stay in the valley Drs. Wilson and Chowning were able to perform a number of autopsies, the details of which are carefully registered in the report before us. The histological study of these cases showed fairly constant, but not altogether characteristic, appearances. Enlargement of the spleen and general congestions were noted, and in all cases small wounds of the skin were observed, due to tick bites. Various bacteria were found in careful routine examination, which did not tend to throw much light on the disease. A most thorough study of the blood was made and confirmatory experimental work done. From these various sources of information it was finally determined that

in all probability the disease was due to a hematozoön, of which the normal host was the gray gopher, indigenous and abundant in that region. The animal is averse to swimming, hence its practical limitation to one side of the river which runs through the valley. Early in the spring the gopher is said to harbor large numbers of ticks, which apparently later in the season is not the case. Of forty-three gophers examined, nine showed within their blood cells hematozoa, which were indistinguishable from the hematozoa found in patients suffering from spotted fever. Gophers examined from the unaffected side of the valley did not disclose similar hematozoa.

The general conclusion reached by this investigation is that in all probability the curious disease under consideration is due to an organism which has as its host the gray gopher, and which is transmitted to man through the bite of the tick. The writers naturally recognize that their work is as yet in a somewhat formative stage, and that further research must be undertaken before their ingenious hypothesis may be definitely established. Experience in other diseases, however, would lead to the assumption that the hypothesis, reinforced by the evidence already at command, is an extremely likely one. They insist that ticks must be most carefully studied ; and particularly those on the west side of the Bitter Root Valley, which have actually bitten persons, should be preserved and identified. In general, the problem is one which already has its analogies, but we cannot too highly commend the scientific spirit in which it has been carried out and the positive addition to knowledge which the substantiation of the hypothesis will bring.

A DAILY MEDICAL JOURNAL.

IT is announced, as stated in our issue for last week, that a medical periodical, to be known as *The Daily Medical Journal*, is to be published, beginning the first of October. The last few years have seen many changes in medical journalism, particularly in this country. Journals have multiplied beyond the demand. Many of the older established periodicals have increased the number of their reading pages, and the general medical activity of the times has been adequately reflected in the various weekly and monthly medical journals. In view of these facts we are not altogether surprised to be brought face to face with a daily medical journal. The need of such a journal, so far as the further development of medical science is concerned, is not in the least apparent, but we suspect, from the statement which has been published, that the object of this new periodical is not purely medical and is not designed solely to further the needs of medical science.

If the statement published in our issue of last week be correct, it is evident that other motives than those ordinarily accepted in the best medical journalism are at work. This we regret. Possibly it is a sign of the times, but it is nevertheless to be deplored that within the last few years a certain departure from the recognized standards of medical publication, which had hitherto prevailed and been accepted, has occurred. We are quite convinced that there is not sufficient medical news of vital interest to the profession to justify a daily publication; nevertheless we shall await with interest this new venture in medical journalism.

LEGISLATION AGAINST THE TOY PISTOL.

EACH succeeding year sees the usual number of casualties resulting from the use of the toy pistol during the weeks about the Fourth of July. There has from time to time been a somewhat lukewarm effort to abate not only the nuisance which such pseudo-firearms produce, but also to check the positive mortality which inevitably results from their free use in the hands of the young. Noise may possibly be a necessity to be indulged in and condoned once yearly, but we certainly have not the right to condone also the really alarming death rate which apparently is an inevitable accompaniment.

We are glad, therefore, to note that the city of St. Paul has shown a disposition to attack the problem seriously through restrictive legislation. It is reported that the corporation attorney has drafted an ordinance which prohibits on the Fourth of July, and it is to be hoped on other occasions as well, the use of blank cartridges and pistols. The ordinance is designed not only to prohibit their use, but also to hold dealers responsible for carrying them in stock a month previous to July Fourth, infringement of the ordinance being punishable by fines.

It is needless to say that such local legislation can have but small effect upon the generally recognized evil, but it is none the less necessary that a beginning should somewhere be made in passing laws of so stringent a character that

evasion will no longer be attempted, and dealers in such objects will be prevented from exposing them for sale. No doubt if the suggested ordinance is a success in St. Paul, it will be adopted by other cities, so that in time the toy pistol will be tabooed in the same sense that violent explosives and, to a less extent, gunpowder are in the hands of the irresponsible. We see no other way than such widespread public sentiment, finding expression in law, to check the yearly harvest of tetanus, which is becoming increasingly menacing. It should certainly be the work of public-spirited physicians everywhere to urge such legislation.

MEDICAL NOTES.

TYPHOID FEVER IN PITTSBURG. — Pittsburg for some time has been suffering from an epidemic of typhoid fever, which still continues. The water supply of the city is held to be responsible for the disease, which has numbered as many as a hundred victims a week, at least during some weeks of the epidemic.

ABOLITION OF RIVER BATHS. — According to a statement in the *Medical News*, President Lederle of the New York Department of Health has expressed himself in favor of the abolition of free municipal baths along the river fronts, on the ground that a certain amount of infectious disease is contracted through their use and that they therefore are a public menace. The question of doing away with the river baths, which are often polluted, and substituting plunges and shower baths, is now under consideration by the Board of Health.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Aug. 12, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 20, scarlatina 20, typhoid fever 16, measles 36, smallpox 0.

IMPROVEMENTS AT THE BOSTON CITY HOSPITAL. — It is stated that a heating plant of an approximate cost of $12,000 is to be installed at the Boston City Hospital to provide for the South Department.

SMALLPOX IN WAREHAM, MASS. — It is reported that three extremely mild cases of smallpox have appeared at Wareham, two in children and one in an adult, the disease presumably having been brought from a distance. The patients are not seriously ill, and there is apparently absolutely no reason to dread any extension of the disease. Quarantine precautions have been taken.

PAVING OF ALLEYWAYS. — The Boston Board of Health has recently taken action under the act providing that the surface of any private passageway shall be paved or otherwise rendered sanitary at the owner's expense. A number of alleyways have been condemned as nuisances and orders have been issued to have them properly paved and drained, the expense to be borne by the owners and not by the city.

NEW YORK.

A SMALL INFANT. — There was recently admitted and placed in an incubator at the New York Post-Graduate Hospital a male infant which weighed only thirteen ounces, which is stated to be the smallest child ever met with there.

YELLOW FEVER ON A STEAMSHIP. — On the steamship *Basil* of the Booth Line, which arrived at quarantine on Aug. 1, four seamen died from yellow fever after the vessel left Para.

THE CARE OF SMALLPOX PATIENTS. — In a case recently decided in the Fourth Appellate Division of the New York Supreme Court the opinion was given, through the presiding justice, that it is the undoubted duty of a town board of health to take immediate and efficient steps, when smallpox develops within its jurisdiction, not only to furnish care and attendance to persons suffering from the disease, but to protect, as far as possible, the residents of the town from the danger to which they are exposed by reason of its contagious and malignant character. To this end the board of health is authorized to incur any reasonable expense, and the expense thus incurred becomes a charge upon the town. The court therefore held that when the health officer of the town, acting under the authority of the town board of health, orally employs a physician to treat and care for all patients who are then, or might thereafter be, affected with smallpox, assuring the physician that he would be well paid for his services, the town is liable to such physician for the reasonable value of the services rendered by him.

A CASE OF POSSIBLE POTASSIUM CYANIDE POISONING. — A remarkable case is reported from the Eastern District Hospital, Brooklyn. A man thirty-four years old, who is stated to have been deaf and dumb from birth, and who was found unconscious in his room by his

father, was admitted in a state of coma, in which he remained for many hours. It was thought that perhaps the patient had been poisoned by illuminating gas, but this was emphatically denied by the family, and the diagnosis remained obscure until he recovered consciousness, when, if the newspaper accounts are to be accepted, the man actually began to talk, and stated that he had inhaled the fumes of potassium cyanide, with which he was cleaning a bed.

NEW YORK HEALTH DEPARTMENT REPORT. — The weekly reports of the New York Health Department for the month of July show an annual death rate of 19.06 as against 16.54 in June and 21.35 in July, 1902. The corrected death-rate, excluding non-residents and infants under one week old, was 18.71. Among the diseases in which there was a decline in mortality were the following: The weekly average of deaths from diphtheria and croup decreased from 49 in June to 36¾ in July; of deaths from scarlet fever, from 19¾ to 11¾; from whooping-cough, from 7¼ to 4; from pneumonia, from 84½ to 58¾; from broncho-pneumonia, from 52¼ to 47; from acute bronchitis, from 20½ to 13¾; and from pulmonary tuberculosis, from 139¼ to 125¼. Among the diseases showing an increased mortality were the following: The weekly average of deaths from diarrheal diseases increased from 84¼ to 301¼; from diarrhea under two years of age, from 82¼ to 297¾; from typhoid fever, from 7½ to 13¾; from cancer, from 46¾ to 50½; from Bright's disease and nephritis, from 93½ to 95¾; and from organic diseases of the heart, from 87 to 98½. Although there was naturally a considerable increase in the mortality from diarrheal diseases, the number of deaths is smaller than the average for the season, and in the last week of July there were 274 in children under two years, as against 340 in the corresponding week of last year. During the month 1 death was reported from influenza, as against 5 in June.

Correspondence.

NURSING AS A PROFESSION.

BOSTON, Aug. 6, 1903.

MR. EDITOR: I am much interested in the subject of your editorial of July 30, upon "Nursing as a Profession."

Not long since you published a short address made by me to a graduating class of nurses, in which I pointed out to them that it lay with them to choose whether they should practice nursing as a calling, contenting themselves with carrying out what they had learned during their novitiate and applying it to the sick under their care, or whether they should regard their previous training merely as a preparation for further constant study and effort to widen their horizon.

I stated that if they chose the latter view and continued through life their search after knowledge, they elevated their nursing to the dignity of a learned profession

A profession has been defined by good authority as "an employment requiring a learned education."

Applying this definition strictly, a young woman graduated at one of our better training schools may properly claim that she is educated for a profession. Graduation from such a school indicates that after obtaining a good "common school" education she has devoted three years to special studies applying to her future employment.

It seems to me, however, that a man or woman claiming to *practice* a liberal profession should be able to show that they are exercising their calling in a progressive spirit that is constantly carrying them forward and is keeping their minds open and receptive.

This spirit is what keeps a profession liberal, and a nurse having this spirit, coupled with sufficient education to properly direct it, is engaged in a liberal profession; while a physician or lawyer lacking this aspiration and disposition of mind may properly be regarded as merely following a calling, even though his education fitted him for a liberal profession.

When the education provided for the trained nurse finds or inspires this proper disposition and energy of mind in a good proportion of its students we shall find that nursing exists as a profession whether we wish to acknowledge it or not.

It remains for the trained nurse to bring the public to an appreciation of the professional worth of her calling by herself making it a profession. There are many individuals who are accomplishing this in the best way, but a full recognition of the high position of the nursing art will be won only when the majority of those practicing it adopt these advanced standards and act up to them.

Just what the limitations of this nursing profession will be, and what its proper relation to the medical profession, time will show.

Respectfully yours,

ARTHUR T. CABOT.

ARLINGTON HEIGHTS, MASS.,
Aug. 6, 1903.

MR. EDITOR: We have been much interested in the discussion going on in your JOURNAL regarding nursing as a profession, because we have the past year been training young women for the care of chronic cases, having found it almost impossible to obtain nurses competent for this work. "A profession must be capable of progress" (from a letter in your issue of July 16).

Along what lines could nursing progress except those which constitute a medical education?

Nurses might be taught more of anatomy and physiology, of dietetics and hygiene, of mechano-, hydro- and electro-therapeutics, etc.; but would they then be nurses? Suppose a person to be versed in all the branches of nursing which do now or might in the future be supposed to constitute an educated nurse, would it then be legitimate for that person to take the initiative in the care of the critically ill? If so, what would be the position of the physician? Possibly, that of consultant, as you suggested. But would not the person become the physician and be no longer the nurse? And is it not contrary to all good teaching of to-day for a nurse to prescribe or take the responsibility of the case unaided? Even the midwife assumes her charge through ignorance, and we would look askance at a trained nurse who took such a liberty.

We must feel that there can be only one profession whose duty it is to administer to the sick, and that the profession of medicine; and that nursing is a subdivision of this profession, its special function being "to take care of the physicial and mental wants of the sick under the direct supervision of the physician."

Yours truly,

ARTHUR HALLAM RING

Deaths reported, 3,387; under five years of age, 1,450; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,337, acute lung diseases 243, consumption 243, scarlet fever 32, whooping cough 26, cerebrospinal meningitis 8, smallpox 6, erysipelas 3, measles 30, typhoid fever 55, diarrheal diseases 773, diphtheria and croup 68.

From whooping cough, New York 4, Chicago 1, Philadelphia 7, Baltimore 2, Pittsburg 1, Providence 1, Boston 1, Lowell 3, and Lawrence, New Bedford, Brockton, Haverhill, Fitchburg and Revere 1 each. From erysipelas, New York 2, Chicago 1. From smallpox, Philadelphia 3, Pittsburg 2, Fall River 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending July 18, the death-rate was 13.5. Deaths reported, 3,894; acute diseases of the respiratory organs (London) 115, whooping cough 86, diphtheria 49, measles 95, smallpox 6, scarlet fever 31.

The death-rate ranged from 5.4 in Bury to 22.6 in Wigan; London 13.0, West Ham 11.3, Brighton 10.0, Portsmouth 13.6, Southampton 13.3, Plymouth 14.0, Bristol 12.5, Birmingham 14.1, Leicester 9.7, Nottingham 14.6, Bolton 18.6, Manchester 17.8, Salford 15.0, Bradford 12.7, Leeds 15.5, Hull 11.1, Newcastle-on-Tyne 17.6, Cardiff 10.9, Rhondda, 15.7, Liverpool 18.0, Smethwick 8.0.

METEOROLOGICAL RECORD.

For the week ending Aug. 1, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING AUG. 8, 1903.

L. W. SPRATLING, surgeon, C. H. DELANCY and E. M. BLACKWELL, assistant surgeons. Detached from the "Columbia" and ordered to the "Hancock."

C. E. REYNOLDS, pharmacist. Detached from the "Columbia" and ordered to the "Hancock."

H. L. BROWN, assistant surgeon. Detached from the Naval Proving Ground, Indian Head, Md., and ordered to the Navy Yard, Washington, D. C.

K. OHNESORG and J. T. KENNEDY, assistant surgeons. Ordered to the Naval Academy.

C. T. GRAYSON, acting assistant surgeon. Ordered to the Naval Proving Ground, Indian Head, Md.

J. COWAN, pharmacist. Detached from the Navy Yard, Boston, Mass., and ordered to the Naval Magazine, Iona Island, N. Y.

E. T. MORSE, pharmacist. Detached from the Naval Magazine, Iona Island, N. Y., and ordered to the Navy Yard, Boston.

E. MAY, pharmacist. Ordered to the Naval Hospital, Norfolk, Va.

J. A. GUTHRIE, passed assistant surgeon. Detached from the "Vicksburg" and ordered to the "Solace."

R. H. MICHELS, assistant surgeon. Detached from the "Solace" and ordered to the "Wilmington."

G. M. MAYERS, assistant surgeon. Detached from the "Isla de Cuba" and ordered to the "Vicksburg."

RESIGNATION.

DR. EDGAR GARCEAU has resigned the position of surgeon to out-patients at the Free Hospital for Women, Boston.

RECENT DEATH.

GEORGE W. ROLERFORT, M.D., a well-known negro physician of Newark, N.J., has died at the age of forty-three. At the time of his death he was officially in charge of the Newark Almshouse and had a considerable reputation also as a politician. He was born in Virginia, was graduated in the Medical Department of Shaw University in 1890, thereafter studying at the University of Pennsylvania Hospital in Philadelphia. He was a member of various medical societies and was well thought of by his colleagues.

BOOKS AND PAMPHLETS RECEIVED.

A Nurse's Handbook of Obstetrics, for use in Training-Schools. By Joseph Brown Cooke, M.D. Illustrated. Philadelphia and London: J. B. Lippincott Company. 1903.

Hyoscine in the Treatment of Morphinism. By T. D. Crothers, M.D., Hartford, Conn. Reprint. 1903.

The Exact Science of Health Based upon Life's Great Law. By Robert Walter, M.D. Vol. I. New York: Edgar S. Werner Publishing Company; London: Kegan Paul, Trench, Trübner & Co., Ltd. 1903.

The Principles of Obstetrics, a Practical Manual for the Student and General Practitioner. By Stanley Perkins Warren, M.D. Illustrated. New York: William Wood & Co. 1903.

Addresses.

MEMORIAL MEETING TO MORRILL WYMAN, M.D.

ADDRESSES BEFORE THE CAMBRIDGE MEDICAL IMPROVEMENT SOCIETY AT A MEETING HELD AT THE COLONIAL CLUB, CAMBRIDGE, MARCH 23, 1903.

HENRY P. WALCOTT, M.D., CAMBRIDGE, MASS.

I HAVE lately been looking over the work upon which Dr. Wyman had busied himself during the last year or more of his life — a memoir of Dr. William J. Walker. The reasons he gives for undertaking the work are thus stated: "Dr. Walker was a man of great and varied abilities; he was my father's friend; he was my friend and benefactor. I cherish his memory as a sacred trust; and as my medical father, would hold towards him the true spirit of the oath of Hippocrates." To some of us these words come home with special meaning, for we were pupils of Morrill Wyman, and know that the Hippocratic oath and the law were to him as sacred things. To all here he was teacher, friend or example of the good and wise physician. Born at Chelmsford on July 25, 1812, he died at his home in Cambridge on Jan. 30, 1903. He was the second son of Rufus Wyman and Anne Morrill. With his younger brother, Jeffries, he was prepared for college at Phillips Exeter Academy. Both entered Harvard and were graduated with the class of 1833. The class of 1833 was a noted one. It gave six professors and four overseers to Harvard University and a president and four professors to other institutions of learning. This intimate association of the brothers lasted through life, and until Jeffries Wyman's death in 1874, the brothers were never far apart, and each exercised a strong influence upon the other.

Rufus Wyman, graduate of Harvard College in 1799, was a favorite pupil of Dr. John Jeffries of Boston. Resisting a flattering invitation from his teacher to establish himself in Boston, he settled in the town of Chelmsford and began the practice of medicine. His abilities were soon recognized, and he gained a reputation which extended far beyond the limits of the town. He was chosen in 1817 to be the head of the McLean Asylum for the Insane. After a most faithful and successful service there of seventeen years, he resigned his place and passed the rest of his life in Roxbury, where he died in 1842. He was president of the Massachusetts Medical Society, and universally respected. It is not easy now to realize what a task Rufus Wyman undertook. One of the greatest of his successors, Luther V. Bell, uses these words: "Entering on his duties with no similar undertaking for an exemplar to guide him in interior arrangements or general management, the weight of difficulty and responsibility which necessarily fell upon him must have been far greater than any of his successors in such trusts, who have had the aids of his ingenuity and labor, can have experienced. What is due to his memory as a public benefactor can never be realized or appreciated, except by the small number whose opportunities and duties enable them to judge of the difficulties he encountered and the measures he projected to meet them." Dr. Bell also adds: "There was in his character not only this strict integrity, but a hatred of ostentation, an avoidance of anything that could be construed into self-laudation, which was carried perhaps to an extreme actually prejudicial. He had such a dislike to newspaper notoriety, such distrust of any form of reputation higher with the public than with his professional brethren, the sole adequate judges of character in a medical man, that perhaps the light of his good works was too much hidden under a bushel to serve its proper end as an example." Forty years later Lowell wrote of the younger Wyman: "The wisest man could ask no more of fate

> "Than to be simple, modest, manly, true;
> Safe from the many; honored by the few;"

and later still, in his own extreme need, experienced from the elder brother, then seventy-nine years old, a devotion and tender care which he did not tire of commemorating in his letters to his friends.

Brought up in such surroundings, the brothers naturally turned to the study of medicine, but not until Morrill had spent several months as a member of a party of engineers who were employed in laying out the route of the Boston & Worcester Railroad. This experience was one that he was fond of reverting to, and nothing pleased him more in later life than to get out his surveying apparatus and show that he had not lost the skill acquired in the occupations of his youth. Under the direction of his father and his father's friend, William J. Walker of Charlestown, he began the study of medicine, and received his medical degree in 1837. Dr. Walker, a graduate of Harvard College in 1810, had had also the advantages of a medical education in France and England during the years when Corvisart, Pinel, Laennec, Dupuytren taught in the one capital and Sir Astley Cooper in the other. Walker's success in his profession was great, and until he suddenly abandoned his practice in 1846 he was one of the leading surgeons of the state. Whatever may have been Walker's failings in any other direction, his relations to his favorite pupil were such that the latter cherished for him an admiration and devotion that never wavered.

For a year Wyman was house physician in the Massachusetts General Hospital, where he had the good fortune, never forgotten, of serving under James Jackson, "the model of the good and wise physician," and Jacob Bigelow, "the most accomplished man of our profession." The house surgeon of the year was Samuel Parkman, an intimate and much-loved friend, whose death in the prime of early manhood took from our profession one of its brightest ornaments. Upon leaving the hospital, he at once established himself in Cambridge, and remained

here to the end. The struggle which the young physician usually has in the first years of his practice to make both ends meet was not his. Prudent habits, an indomitable industry, the family name, an engaging presence, the good will of the leaders of his profession, which he had fairly earned,— all these stood him in good stead, and he never had from the beginning any reason to be anxious about his money affairs, nor, indeed, did he ever pay much attention to them. He had all the qualities which make successful men of affairs, and he might have rivaled the wealth of Walker; but his ambition never led him in that direction. Throughout his life he was indifferent to the luxuries which money could procure. The utmost simplicity pleased him best, and his property grew because he had a large income and did not waste it. The investment of it never occupied much of his attention. He was generous, but he was too frugal in his own habits not to demand the same care of others. He was one of the large contributors to the Cambridge Hospital, and many a house in this city cherishes the memory of the silent benefactor, who also gave them something far beyond the perfunctory contributions of money which often pass for charity. Though his early professional life was a busy one, he found time to compete for the Boylston Medical Prize, which he received in 1846 for an essay on ventilation. This was published in the same year, increased to a volume of 400 pages. It is a thoroughly original treatise, illustrated by a number of original experiments. Dr. Billings, one of the best authorities upon the subject, says of this book that it is one of the most valuable that we have; that it states the general principles of ventilation in a clear, concise style and in a form which as a manual of instruction for the ordinary reader can hardly be surpassed, and is one of the few books on heating and ventilation which advocates no patent or proprietary apparatus. One of the most valuable and extensive series of experiments upon the effect of various forms of outlet cowls for chimneys was made by a committee appointed for that purpose by the American Academy of Arts and Sciences. The report of this committee was prepared by Dr. Wyman, and will be found in the proceedings of the Academy for 1848. It is still quoted in the best treatises upon heating and ventilation. The interest which he thus early showed in a subject of prime importance to both the sick and the well remained with him through life. A few weeks only before his death he was busy measuring with his Casella anemometer the air currents in the basement of the Cambridge Hospital. For years he was consulted upon all important questions of ventilation in this vicinity, and probably nothing could distress him more than some violation of the principles of ventilation, for which some might wrongly suppose him to be responsible.

At a later day he again entered the field as a competitor for a prize offered by the Massachusetts Medical Society, and made possible by the liberality of one of its fellows. The prize was for an essay which should describe in plain language an effective and ready method of ventilating sick-rooms; one that can be put in operation at once at the needed moment, with least difficulty and expense, in houses of ordinary construction. Twenty-six essays were received, and to one marked "X Y Z" the prize was awarded, this having met all the requirements of simplicity, cheapness, effectiveness and readiness of application. "X Y Z" declined to reveal his name and requested that the prize money be expended in the publication of the essay. For those familiar with his language and his methods, the letters were only a thin veil before the man who made it his business at all times to use a phraseology so plain that all might understand it.

This capacity for clear statement made him one of the most effective of expert witnesses in the courts of law; a position, however, which he never sought, and only occupied when he thought some gross act of injustice might be averted by his intervention.

Both his father and mother and other members of his family in his own generation suffered from pulmonary affections. Before 1850, two slight hemorrhages from the lungs warned him that he, too, was in danger. His family and his friends were urgent that he should take some respite from his severe labors. Beyond a short vacation, the first that he had taken since entering upon practice, followed two years later by a few months in Europe, he could not be induced to yield to his own safety, but returned to enter again upon a practice larger than before. An active life of exposure in all weathers, in which he wholly disregarded regularity of habits in eating and sleeping, so far from confirming his malady, seemed to bring him a cure, and he lived to his ninety-first year with fewer apparent disabilities than fall to the lot of the majority of men.

An operation for opening the chest, in order to remove accumulations of fluid there, had been known to medicine from the days of Hippocrates. It was dangerous in execution and uncertain in its results. With the greater knowledge of all diseases of the chest consequent upon the discovery of modern auscultation and percussion, it had seemed to many men that a safer operation than the one in use might be devised. This had not, however, been accomplished. Dr. Wyman had thought much upon the subject, and on the 23d of February, 1850, put into use the simple operation which he had invented. His patient was a lady in Cambridge, suffering much from a collection of fluid in the chest, which showed no tendency to absorption. She was in a critical condition. He called in consultation his friend, Dr. John Homans. It was agreed that the patient's condition was most serious. Dr. Wyman proposed a puncture of the chest. The older physician was reluctant, but finally offered to return to Boston and

to consult with some of his medical brethren upon the subject. Later in the day he returned and announced that though none of his Boston friends could from experience advise it, he was willing to take his share of the responsibility for an operation. Dr. Wyman accordingly punctured the chest with an exploring needle and canula, and drew away twenty ounces of a straw-colored fluid. The patient improved. Two days after the operation she had occasional paroxysms of dyspnea, and at her earnest solicitation the canula and exploring needle was again inserted. This time the canula was fitted to a pump so contrived that fluid was continuously drawn through it without the possibility of the entrance of air. Ten ounces of clear fluid were drawn, with immediate relief to the patient. The recovery was uninterrupted. Dr. H. I. Bowditch had bestowed much thought upon the same problem. He heard with pleasure of his friend's success, and asked him to perform the same operation upon a patient of his in Woburn, who had consulted Dr. Bowditch in similar circumstances to the Cambridge case. Accordingly, on the 17th of April, the second operation of thoracentesis was done and Dr. Bowditch at once recognized its value. With characteristic modesty, Dr. Wyman felt that his task, so far as it related to the general publication of the merits of the new operation, was complete. He knew that his friend would see to it, as he did, that the medical world should be fully acquainted with the discovery. He knew, also, that no credit to which he had a claim would be taken from him, and it would have been an undeserved indignity to both to have even hinted at the possibility of it.

From 1853 to 1856 he was adjunct Hersey Professor of Medicine in Harvard College, for the purpose of relieving Dr. John Ware, whose infirm health required assistance in his duties. During the year of Dr. Ware's absence, Dr. Wyman gave all the instruction in this department. In 1856 he resigned his office. The methods of the medical school of that day do not appear to have been altogether congenial to him, and he was always inclined to be restive under restrictions which did not commend themselves to his reason. But whatever may have been the causes of his early withdrawal from a professorship in which he had been eminently successful, they never led him to lose his interest in the teaching of medicine in the university. In the early part of 1857, in connection with his brother Jeffries, Hersey Professor of Anatomy, Dr. John Ware and Prof. J. P. Cooke, he became a teacher in a school of medicine in Cambridge, he giving the instruction in materia medica and midwifery. The school had a fair measure of success, and a list of students whose names are well and favorably known to-day in many parts of the country. Few schools of this description have contained a more distinguished body of instructors than did this one. Besides the four names above mentioned are those of Profs. Lovering, Gray and Agassiz. When Jeffries Wyman assumed the curatorship of the Peabody Museum, the school came to an end. In fact, the real inducement that led Morrill Wyman to take part in this school was probably the desire to give to his brother a somewhat larger field for the teaching of anatomy than that offered by his college professorship.

In 1860 Dr. W. J. Walker offered to give to the college, under conditions which do not seem to have been unreasonable, all that remained to him of the earnings of his professional life, for the purpose of improving the condition of medical education. Dr. Wyman was greatly interested in the proposal and did all in his power to promote the undertaking which lay so near to the heart of his loved and honored master. The medical school, however, was not ready to follow a great leader, and ten years more were to pass by before there came to the administration of all the affairs of the university a mind that could fully appreciate Walker's grand conceptions. Walker, however, was dead, and five other educational institutions had profited by the munificent gifts which Harvard had rejected. A succession of reports made by Dr. Wyman to the board of overseers upon the affairs of the medical school, even down to the last years of his life, are evidence of his continued interest in it. It was an unending regret, however, to him that Walker could not have been permitted to see the new day, and to contribute to the support of a teaching of medicine which accorded so well with his own ideas. In one of these reports made in 1898 he records his final opinion of the methods of medical teaching. No one preparing for the medical profession can overestimate the value of laboratory training. Anatomy, the study of the machine; physiology, the machine in action,— are the work of the laboratories. The art of observation, the medical education of the senses, as it has been called, is more valuable as a mental training than all didactic lectures put together. It is the best training for the practice of medicine as an art, as a science and for research. Laennec made and carefully recorded nearly four hundred autopsies before the sounds heard on the chest by his educated ear were properly connected with the morbid changes within. Auscultation could have been invented in no other way.

Upon no work of his life did he bestow more thought than upon the annual address delivered before the Massachusetts Medical Society in 1863. His father had received the same honor in 1830, and had made it the occasion for a statement of the great work of his life. The son took the same serious view of the opportunity offered to him. Three years before, the orator of the society was O. W. Holmes. His exposition of the state of medicine was, it is needless to say, brilliant in the highest degree. He himself said at a later day that he had somewhat too epigrammatically for some of his friends of the Massachusetts Medical Society denounced the practice of drugging for its own

sake, and it is undoubtedly true that a mischievous use was made of the orator's seductive eloquence. It was in any case the effort of one who had viewed the practice of medicine somewhat from the outside. Dr. Wyman undertook the defence of his art as one who knew it thoroughly and believed in it, and there is not one in that long series of anniversary addresses more worthy of notice and faithful study.

With some other members of his family he had been a lifelong sufferer from an autumnal catarrh, corresponding in its symptoms to the affection described by Bostock in 1819 as catarrhus estivus, rose, hay, or June cold. The form of the disease from which Dr. Wyman suffered had not hitherto attracted the attention of medical men and was first accurately described by him in his lectures to the students of the medical school in 1854. In 1866 he brought the subject to the attention of the Massachusetts Medical Society, and gave to the malady the name of autumnal catarrh, adopting the general nomenclature of Dr. Bostock, a title which commended itself much to his favor because it involved no theory as to the cause of the disease. In 1876 he published a volume of 900 pages upon the subject. The quality of the book may be inferred from the quotation from Sydenham which he prefixed to it: "In writing the history of a disease, any philosophical hypothesis whatever that has previously occupied the mind of the author should be in abeyance. This being done, the clear and natural phenomena should be stated; these and these only."

In 1859 there occurred in eastern Massachusetts some cases of pleuro-pneumonia in cattle, which were supposed to have their origin in an infected animal brought from Holland to a farm in this neighborhood. Much alarm arose in consequence among the farmers of the state, and the public authorities dealt with the epidemic in much the same fashion that has lately been the case with the foot and mouth disease. Dr. Wyman was convinced that the extreme measures adopted were not justified by the existing knowledge upon the subject, and urged, as he always did, the need for accurate observation and intelligent experiment. Then, as now, the authorities believed observation and experiment to be sources of danger, and Dr. Wyman was only enabled to carry out a very modest series of experiments upon diseased and healthy animals upon his own estate in Cambridge by authority of a resolve of the Massachusetts Legislature. For this purpose a shed was erected upon his own grounds on Sparks street, and two cows suffering from the disease were procured and placed here with five others apparently sound. They were all kept under careful observation for three months and then killed. The post-mortem examination showed extensive destruction of the lungs of the two cows known to be diseased and a similar morbid process in one of the animals believed to be sound. The remaining animals were in healthy condition. From his experiment, admittedly incomplete, he draws several conclusions, one of them so characteristic that I quote it: "In a commercial point of view, it would have been unwise, so far as the herd was concerned, to kill all the animals as soon as exposed, whether we have regard to the value of the animals recovered or the number which apparently became diseased in consequence of exposure. These are the conclusions to which a believer in the contagious nature of the disease would assent. These experiments have been undertaken not without considerable expense and trouble; they are offered as a contribution to our knowledge of a most important disease among cattle, with the hope that they may be continued until definite results shall be arrived at, not only as to its contagion or non-contagion, but also with regard to other points interesting in an economical point of view, and not less so as it bears upon the study of comparative pathology."

In 1871 sufficient interest had been excited by Miss Emily Parsons' efforts to establish a hospital in Cambridge to induce a number of citizens to procure an act of incorporation for the Cambridge Hospital. In 1874 Dr. Wyman became interested in the plan, was elected president of the board of trustees, and the establishment of a hospital was assured. In 1883 the land was bought, and in 1886 the hospital was opened for the reception of patients. At the age of eighty he resigned the office of president of the board, but continued his interest to the last. Many good citizens have labored for the establishment and maintenance of this charity, but they would all, I think, admit that Dr. Wyman's presence upon the board — and that inevitably meant ceaseless activity — was the most valuable contribution made to the hospital. His work in connection with the plans for the hospital revealed one of the most remarkable characteristics of his later life. He was chairman of a committee of the board appointed for the purpose of preparing plans for the buildings. He had arrived at certain results, and was satisfied with his plan. It was then suggested that a visit be made to the buildings then in course of erection for the Johns Hopkins Hospital, under the direction and in accordance with the plans of that great master J. S. Billings. The visit was made, and after a day spent in the critical examination of the hospital, this clear-seeing brain, though in a body seventy years old, rejected all its own carefully elaborated conclusions and at once set to work to devise improvements in the new scheme which he had substituted. I know of no more striking feature in his wonderful old age than the absence in both brain and body of the defects consequent upon long life. The past was full of pleasant thoughts, and he delighted to recall it at times, but he looked towards the future with all the confidence of youth, and though he had lived through a period which had seen all the great discoveries in medicine, with the exception of vaccination, he was firm in the conviction that greater things even were yet to come.

One substantial addition he did make to the ventilation system of the hospital which can be applied to any plan for the removal of foul air at or near the floor level. It is extremely ingenious and, like most of his contrivances, quite simple. The invention consists in the connection of the inside of the bed with the outlet ducts by means of a flexible tube. The porous bedclothing offers a sufficient obstacle to the free passage of air to prevent any sensation of draft on the part of the patient. A paper entitled "Some Experiments and Observations on the Summer Ventilation and Cooling of Hospitals," presented to and published by the American Academy in 1894, is also founded upon work done in connection with the hospital. This, his last communication to the Academy, was published at the expense of the Rumford fund. Early in his career he was elected member of the Academy, and was for many years the most active member of the Rumford Committee of that body. I will read the concluding sentences of this last paper. "The experience of the Cambridge Hospital leads to two conclusions: first, that fresh air directly from the open, in the quantity and manner thus supplied, can be made to give great comfort to the sick during the heat of summer; and secondly, that previous cooling of the air so supplied is difficult and practically useless. To this may be added, what is of much importance to charity hospitals, that the method here adopted is the least expensive of the cooling processes hitherto made generally known."

He prepared and presented to the Academy in 1887 an elaborate memoir of his friend Daniel Treadwell, of some two hundred pages, which appeared in the series of publications of the Academy. Treadwell probably has had less popular recognition than any other great inventor, yet to this comparatively unknown man the country owes the first prosperity of its railroad system. On printing presses originating from his invention nearly all our books are printed; machines of his device revolutionized the art of rope-making as completely as those of Arkwright revolutionized cotton-spinning; the most effective artillery of modern warfare is made upon principles which he first discovered and applied. In 1825, acting under the authority of the mayor and Board of Aldermen of the city of Boston, Treadwell investigated the subject of a general water supply for the city, and submitted a report, the first public one made on this important subject. Valuable as the report was, the community was not yet prepared to enter upon so considerable an undertaking, and nothing was done until Mayor Eliot in 1837 energetically brought the matter to the attention of the city government. Mr. Treadwell was made chairman of a committee to consider the subject anew, and the movement ended for the time being in the construction of the Cochituate water works in 1848. Treadwell had many of the qualities which were peculiar to Dr. Wyman. The tendency of his mind was essentially experimental. He had the ingenuity of the mechanical inventor and the philosopher's passion for truth. In May, 1865, Treadwell received from the Academy the Rumford medals, one of gold and one of silver. These medals, during the preceding thirty years that the Academy had been charged with their award, had been given to but two persons; never before to a member of the Academy. To him they were given for "Certain Improvements in the Management of Heat." Dr. Wyman was an active member of the Rumford Committee of the Academy, and took great satisfaction in helping to obtain for his friend this well-earned and grateful reward.

He was interested in all the affairs of the community in which he lived, but he never allowed them to interfere with the real business of his life — the care of the sick. In 1866 the whipping of a girl of sixteen in one of our public schools attracted the attention of the citizens and filled Dr. Wyman with a righteous indignation. The school committee declared the punishment to be strictly within the rules established for the government of the schools, and were unwilling to change those rules. By all reasonable means a number of citizens, among whom he was foremost, endeavored to secure from the committee some regulations sufficient to prevent tbe corporal punishment of a young woman of this age. All efforts were in vain and, as a last resort, Dr. Wyman carried in a Republican caucus a resolve that the corporal punishment of girls should be abolished in each and every public school in this city. The next city election changed the character of the school committee, and a more humane rule was established. His efforts in this cause were always remembered by him with great content, and rightly so, for to him, more than any other man, belonged the credit of the reform. He had through it all, and much appreciated, the cordial support of his old, close and tried friend, Dr. Wellington, to whom the public schools of Cambridge owe so much. Two of the public schools of this city now bear the names of Wellington and Wyman.

In 1857 he had acquired the collection of books which Tiedemann of Heidelberg had brought together. Tiedemann was one of the great anatomists and physiologists of the world, and his library was of great scientific value. Dr. Wyman was led to purchase it, not only for the aid that it might be to himself, but also from the feeling, never absent, that his brother Jeffries could profitably use this at that time unrivalled collection of original works upon comparative anatomy and physiology. In 1893 Dr. Wyman gave this library, with some additions from his own medical books, to the Cambridge Library. He hoped that the collection might be soon supplemented by publications containing the recent discoveries, and the most valuable current literature. It now appears probable that the city cannot, with a due regard to the other claims necessarily made upon a public library,

provide for so expensive a development of one department, even so important a one as this. The gift, however, remains an evidence of his loyalty to the place of his residence, and to the highest interests of his brother practitioners of medicine there.

At eighty-five he regarded himself as no longer subject to the calls of those seeking medical assistance. As a matter of fact, he recorded in his case book the attendance upon a limited number of patients as late as June, 1902. Rest in the sense of inactivity was impossible for him, and his activities had always some definite and useful object in view. It might be an observation upon the ventilation of the hospital, or possibly he was busy over some disabled mechanical contrivance which his deft hand could still correct. He was a member of the board of consultation of the Massachusetts General Hospital at the time of his death, and was much pleased by the earnest desire expressed upon one occasion by its trustees, that he should assume the care of the McLean Asylum. If he had consulted his own wishes alone, it is not unlikely that he might have accepted the offer of a position which would have compelled him to sacrifice a very large and remunerative practice. He was always active in the council of the Massachusetts Medical Society, and by an interesting coincidence an important measure proposed by him at a previous meeting of the council was unanimously adopted at the meeting to which the president of the society announced his death.

The Cambridge which he first knew was a village; when he died it was a great city. He had lived through great events in country and state and city; had watched them all with eager eyes, sometimes inclined to blame, but more often to improve. He was a good citizen and interested himself in the first duties of a citizen. On the cold, bleak morning of our last municipal election he quietly walked over to the polling place and cast his vote before most of his neighbors were astir. Among the various interests that centered in Cambridge, no one was greater, next to his patients, than the college and his friends who were in charge of it. Intimately associated with all the great men who during the past sixty years and more have taught here, he had himself served the university in many useful capacities. Professor from 1853 to 1856, he was elected member of the Board of Overseers in 1875 and reëlected in 1881. In 1885 the college bestowed upon him its highest honorary degree, and he was a member of the overseers' visiting committee to the medical school and active there until his death.

He attended through life the services of the Unitarian Congregational Church, but he found it impossible to attach great weight to any ecclesiastical authority in matters of religious belief. His professional life had brought him into contact with men and women of many beliefs, and he had found in all of them so much to respect that he would have hesitated to criticize what after all seemed merely a question of form. He was a profoundly reverent man. Nothing which his fellows deemed sacred was capable of being turned to a jest by him. The motto on the seal of the Cambridge Hospital was chosen by him: "Man tends; God mends," and the belief was as real to him as to the great surgeon from whom he borrowed it. The record of his services to medicine and our medical charities will remain, but for us, his friends, there is something more than this. We shall long remember the well-built, well-kept figure, the serious but kindly and always impressive face, the alert and vigorous movements of the body that never grew to be infirm, and above all, the man, tender-hearted, tireless in service, sagacious, full of courage, impatient of opposition perhaps with regard to questions upon which his mind was made up, and sometimes aggressive, but never forgetful of the rights or interests of his brother physicians. He went out of his way to help the young beginner, and was the first to bring comfort to his older associates when in trouble or in suffering. With no thought of his own renown he believed himself under a sacred obligation to defend the fair fame of those who could no longer speak for themselves. No person in the wide circle of his acquaintance ever doubted that he would speak the truth that was in him, or fail to acknowledge the truth that was in another; and lastly, in his own words, taken from his address before the medical society, I find him well portrayed: "Half way between the extremes in his profession, those who have an unbounded faith in imaginary remedies and those who reject all medicinal agents, stands the rational physician. Removed from the credulity of the first and the scepticism of the second, he feels that his profession is a noble and a glorious one; and inspired with a just confidence, he looks forward to the time when some of its high aims and aspirations shall have been accomplished. He sees in remedial treatment a blessing vouchsafed to the human race. Whether this blessing shall reach those who commit themselves to his care, he believes depends in a good measure upon the ability with which he has searched out the secrets of nature and the faithfulness with which he learns her powers, both those within the body and those which have been accumulated and stored up in the various remedial substances against her hour of need. With the Hippocratic oath he declares, 'With purity and with holiness I will pass my life and practice my art. I will follow that course of treatment which, according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous.' Cheered by such hopes and sustained by such faith, he seriously and thoughtfully girds up his loins for his work. He meets firmly and uncomplainingly the labors, privations and dangers inseparable from his calling, feeling in his inmost soul that no life can be better spent than that devoted to the relief of his suffering fellow beings."

DAVID W. CHEEVER, M.D., BOSTON.

So complete and so perfect a memorial account has already been given of Dr. Morrill Wyman that I may be permitted to be more discursive in my remarks; and his death at an age so advanced will afford me a theme for a few words on the older members of our profession. While I have been practising medicine in Boston, one hundred and thirty-six physicians, whom I have personally known in this community, have died. Of these, three attained the age of ninety years; while one honored member, Dr. William Ingalls, still survives beyond that term. Dr. James Jackson reached his ninetieth year. The three nonogenarians are Dr. Walter Channing, Dr. Jacob Bigelow, Dr. Morrill Wyman.

We may confidently say that Drs. Jackson, Channing, Bigelow and Wyman, to place them in the order of seniority, were leaders in the medical profession. No men of their time were more prominent. They began life early, and they lasted long. Simple habits, less luxury, out-of-door life, a more quiet age, conduced to longevity. These men accomplished much, but they wrought slowly. What has been better brought out than Jackson's "Hints to a Young Physician"; Channing's "Bed Case"; Bigelow's "Self-limited Diseases"; Wyman's "Hay Fever" and "Ventilation"?

These lives cover the greater part of the nineteenth century. What changes in knowledge and in practice during that time! Bleeding and drugs: expectant nihilism: germs and antitoxines, mark three epochs in that century. These old observers, these clear thinkers, these medical philosophers can well teach us a lesson of patience, tolerance, thoroughness. Jackson, Bigelow and Wyman were pure types on the general practitioner. Dr. Channing was an obstetrician.

Before hospitals existed, their memory was undisturbed by the hasty diagnosis of a hundred cases seen in a single morning. Their observant powers were concentrated on a few cases. Problems were simpler; differentiation less; there were no specialists; blood was drawn, but not examined, save for the "cupped and buffy coat" of inflammation; urine was inspected, but not analyzed; sputum was considered, but not microscoped; and during their earlier years auscultation was unknown. Fever was an entity, and suppuration the rule. There were no alkaloids ready to hand; there were very few proprietary medicines; remedies were slowly and laboriously compounded, and pharmacology was their daily study.

Beginning very young, and studying under one master, they imbibed his traditions and his experience. These older men were strong in well-focussed powers of observation, in the "tactus eruditus," in prognosis, in the art of speech which conceals opinions; cautious, deliberate, guarded, slow to promise, faithful in attendance, as a rule uncommercial, considerate; the family physicians, as advisers, friends, confessors.

The tardy messenger called at their office to summon them forth on foot, on horseback, with a horse and chaise. The telephone, the trolley car, the automobile concerned them not. They slowly spelled out their thoughts on paper without a stenographer, a phonograph or a typewriter. What was done was done slowly, thoroughly and stood permanently. The stethoscope, the thermometer, the microscope were either unknown or in their infancy. The use of the unaided senses sharpened them to an acumen not now common.

Now all is detail, precision, differentiation. The modern is best, but it is sometimes hasty. The older is to be respected for what it did in preparing the way for a newer philosophy. Neither must it be forgotten that these, our medical fathers, and their contemporaries laid the cornerstone of our hospitals; formed and developed our medical schools; originated our medical societies, our rules of ethics and our fee-tables; and passed through and left behind many periods of mysticism and superstition in medical theories.

R. H. FITZ, M.D., BOSTON.

In paying tribute to the memory of Dr. Wyman it has seemed to me fitting to say something relative to his connection with the medical school, in which for a short time he was a valued teacher in the department of theory and practice. It is evident that he regarded this position as one of honor, since in 1872, sixteen years after his resignation, there is imprinted with his name on the title-page of his work on autumnal catarrh, "Late Hersey Professor Adjunct of the Theory and Practice of Medicine in Harvard University." In August, 1853, Dr. John Ware, then at the head of this department, asked for assistance on account of the state of his health. In November of the same year, it is stated in the records of the faculty that Morrill Wyman, recently appointed adjunct professor of the theory and practice of medicine, was present at a meeting of the medical faculty. From that time until the fall of 1856, when he resigned his position, he was a frequent attendant at the meetings of the faculty, served on its committees, and in 1854 was appointed to give the introductory address at the commencement of the annual course of lectures. It would seem, also, that during the following winter he took entire charge of the instruction in this department, for it is recorded that Dr. Ware was then in Europe.

It has not been my fortune to have learned from any of the students of that time what were the characteristics of Dr. Wyman's teaching. It must have been earnest, honest, logical, practical and thorough, for these were his qualities. He was the rational physician who, to paraphrase his own words, had devoted his time and his talents to a laborious preparation for the duties of his calling. He was imbued with a sense of its dignity and of his own responsibility. He knew when to refuse remedies that are useless or dangerous. He was familiar with the ways by which nature brings health from disease, and by weight

of his character he imparted confidence and commanded respect. We know that he attached especial importance to a knowledge of pathological anatomy as the foundation of the study of disease, and took every opportunity of illustrating this part of his teaching by models, drawings and recent morbid specimens. Several years ago he gave to the medical school his diagrams especially prepared, evidently at considerable cost, for the above purpose. A recent examination of this collection shows that it consists of numerous colored, much-enlarged reproductions of plates representing the diseases of the various organs of the body, and selected from the classical works of Cruveilhier, Carswell, Bright and Hope. The interest thus shown in morbid anatomical changes and the importance of a knowledge of them as a means of controlling errors of observation or laxity of judgment, remained throughout his life. Whenever possible he availed himself of the opportunity of applying the test of a postmortem examination to clinical observations, and thus qualified himself for that thoroughness of investigation and correctness of inference which made him a model of caution and wisdom in his numerous medical consultations. His interest in physical and physiological subjects and the practical bent of his mind led him to recognize therapeutic possibilities, and a considerable part of his teaching related to the treatment of disease. The doctrine announced in his annual discourse before the Massachusetts Medical Society in 1863 on the "Reality and Certainty of Medicine" could not have been widely different from his teaching of the previous decade. "If the disease proceeds regularly and safely, the duty of the physician is to hold his hand, be cautious and watchful, see that all dangerous complications are avoided, pains relieved, comforts increased, the strength husbanded, and the disease brought to a happy termination."

Unfortunately for the medical school, Dr. Wyman felt impelled to withdraw after three years of interesting and satisfactory service. This action was contrary to the wishes of his colleagues, who formally expressed their great personal regard and esteem for him and their respect for his abilities as a teacher. Dr. Wyman's professional career then came to an early close, in the fulness of his powers, and at a time when larger opportunities were near, for two years later the Hersey professorship was resigned by Dr. Ware. Nevertheless his interest in the medical school and in medical education was lifelong. Among the last words spoken to me a few hours before his death, with remarkable clearness and emphasis, were those relating to proposals many years ago, which had they been accepted, would have richly endowed the medical department of the university and doubtless have added largely to its usefulness.

WM. T. COUNCILMAN, M.D., BOSTON.

I have known Dr. Wyman since 1892 and in the last few years have seen him frequently and had numerous conversations with him on subjects in which he was especially interested. He was much interested in methods of teaching; and the modern laboratory teaching, in which a student acquires knowledge of objects from having seen, handled, measured and compared them, strongly appealed to him. He several times came into the medical school, went into the laboratory among the students, looked at their drawings and showed great interest in their work. He said to me, "These men are using their senses and that is the only way by which knowledge can be acquired." He was also interested in photo-micrography, and the use which could be made of this in teaching by projecting lantern slides made from the negatives. He regarded it as a further extension of the study of the object." "The student should always see things," he said,—"see what actually takes place in disease and not merely be told about it." On these visits he met the assistants in the laboratory, talked with them about the work they were doing and they received stimulus and encouragement from him. I shall always remember a delightful visit which the entire pathological department made to him one afternoon last November. He had arranged on a table in the drawing-room a number of books containing classical articles in medical literature. Among them was the volume of Guy's Hospital Reports which contained the articles of Bright on typhoid fever and diseases of the kidneys; the monograph of Jenner on vaccination, Laennec's work on phthisis, John Hunter on inflammation. He talked to us of the books and their authors, of his early studies, of the influence which his old preceptor had upon him. We told him what we were doing, and with each he entered fully into the interest of the particular subject. In this intercourse he sought to give the impression that the advantages were his, not ours.

A few years ago a small monograph on diphtheria was published from the laboratory and a copy was sent to Dr. Wyman. A number of letters were received about the work, but from no one came such kindly and intelligent appreciation as from Dr. Wyman. He came to the laboratory shortly after this and left with me the memorandum which he made while reading the work, and which served as the basis for his letter. In the memorandum he had noted what was new in the work and what was of importance. He noted the mixed infections between diphtheria and purulent infections, and wrote: "On such cases antitoxin can have no effect." He also noted the frequency with which tuberculosis, unsuspected clinically, was found in the autopsies on children. Many of the tuberculous lesions could be regarded as healed, and he wrote, "This is interesting and most encouraging in view of the present efforts for improved treatment." On the changes in the Malpighian bodies in the kidneys, he wrote, "I love to see the name of Harvey's great demonstrator. He had no one to teach him where to look for the confirmation of theory. It required seven years' search of his own."

Of late I think his chief interest lay in the study of the structure and function of the placenta. It seemed to me that this interest was partly a reminiscence of his early days as a student under Dr. Walker. Last summer he wrote me, saying he had traced the development of our knowledge of the placenta by the work of the two Hunters, Owen, Dalton, Michael Foster and Vuchow, and desired me to add what I now taught about it. As the placenta hardly comes within my province, I had had no occasion to look up the recent literature and had no special knowledge on the subject. I finally wrote out as clear an account as I could and took it out to him with some diagrams and preparations. We spent two hours on the subject, for in explaining the functions of the organ it was necessary to go at some length into the subject of serum and immunity. No young man could have been more eager, and have shown more readiness in grasping new information. In his medical reading, Dr. Wyman always selected the best things by the best men, and few had such a knowledge of the medical classics. He knew and appreciated the great men of the past and he is now one of them. He sought knowledge by careful observation and sound reasoning. He had what is so often found in great men, a simple, kindly nature. He gave help and sympathy to those who were trying to increase knowledge. Men were better students and better men from having known him.

J. T. G. NICHOLS, M.D., CAMBRIDGE, MASS.

It has been well said that the qualities which mark the good physician are learning, sagacity, humanity and probity. All who knew him will say that Dr. Wyman bore these marks.

For nearly fifty years I was in close association with him as a student and a fellow-practitioner, and would say a few words of him as a teacher. It was for a few years only that he found time to give instruction to medical students. Those who were so fortunate as to have this privilege placed him in the front rank of teachers of medicine.

His great field as a teacher, and one that he cultivated faithfully and never abandoned as long as he lived, was among his fellow-physicians. He had an extensive consultation practice which brought him in contact with a great many. This gave him an opportunity which he used faithfully and wisely. Always mindful of the rights of others, he had the confidence of his professional brethren. When he had to point out errors or shortcomings of the attending physician he did so frankly, but in a way not to arouse his antagonism but to inspire him with the desire to do better work.

He took great interest in our medical societies. He was a regular attendant at their meetings, and the records show that he was a frequent contributor to their proceedings. In these ways he did more than any one in our community, as I believe, to raise the standard of our profession.

This line of Lowell's, written of his brother Jeffries Wyman, applies to him, "Wisely to teach, because more wise to learn." Dr. Wyman even to his last days kept abreast with the advances in medical knowledge. With him education was a life-long business. He was conservative in the best sense of the word, proving all things and holding to that which is good. His judgment as to the probable truth of new theories was singularly good. I give one illustration of this judgment. In 1843 Oliver Wendell Holmes maintained in an essay entitled "Puerperal Fever a Private Pestilence," that this disease was often carried by the physician from one patient to another and that any foul discharge might be carried in like manner and cause this disease. This doctrine, now universally accepted, was strenuously and bitterly opposed. The professor of midwifery in the then leading medical school of the country told his students that they could "never convey in any possible manner a horrible virus, so destructive in its effects and so mysterious in its operation, as that attributed to puerperal fever." Dr. Wyman investigated the subject, and becoming convinced of its truth, taught it by precept and example. He had the power which Hippocrates commends in saying, "I look upon it as a great part of the art to be able to judge properly of that which has been written."

All honor to the memory of the man who so fully paid the debt which Lord Bacon says every man owes to his profession, by leaving it better than he found it.

THE SURGICAL TREATMENT OF GASTRIC ULCER.[1]

BY JOHN C. MUNRO, M.D., OF BOSTON.

IN accepting the flattering honor of discussing the treatment of gastric ulcer before your section, I must plead, as a partisan, for the more intimate association of the internist and the surgeon in the study of this large class of cases. What I shall say will be for the general practitioner. Without hesitation, I venture to predict that within five years my plea will be considered mild and conservative by those of you who would put me down as too radical at the present time.

In the first place, there are certain fundamental facts recognized by the surgeon, but not yet fully appreciated by the physician. An operation as performed on the average patient with a mortality so small that it may practically be disregarded becomes serious or even unjustifiable if done in the presence of persistent hemorrhage, prolonged sepsis, starvation, absorption of ptomaines, etc. These facts are so persistently overlooked by the general practitioner that it seems worth the while to bring it up in connection with the subject of gastric ulcer. Let me, in this connection, repeat a

[1] Read before The Massachusetts Medical Society, June 9, 1903.

statement that I made not long ago before one of our section meetings: that a careful analysis of over a hundred consecutive laparotomies that came to my care at the City Hospital demonstrated that at least 60% came too late from a surgical point of view. Is it fair to lay at the door of surgery all the failures, the tedious recoveries, the inevitable sequelæ, or the deaths that must obtain in such a group of cases?

In the treatment of gastric ulcer, where surgery is indicated, if we grant that in our earlier work, hesitating technique, errors in the selection of cases and in the after treatment, give discouraging or fatal results, we must not lose sight of the fact that eventually we are to look to surgery for the relief or cure of ulcers incurable by medical means, for the prevention or cure of the malignant degenerations and for relief from the thousand and one distressing sequelæ that do not kill, but that make life worse than death.

Up to the present time surgery has by no means solved the whole question of the treatment of ulcer or its complications. There is much still to be learned before we can fairly say that a beginning has been made, but the process of learning must go on with the internist and the surgeon working conjointly in practically all cases of ulcer or suspected ulcer. Later, when both surgeon and physician are educated sufficiently, as is the case in appendicitis for the most part, to enable each to recognize what types are medical and what are surgical, the combined observation will be demanded in a small proportion only of all cases. This is the ideal for which we must strive.

Without hesitation I would agree that the majority of cases are medical theoretically from first to last. To determine where the line should be drawn in the remainder demands a most careful and persistent collaborated study in all cases of ulcer, at least for a while.

It is not my purpose to quote statistics. One can safely state that the results, as regards mortality, from operation are improving almost month by month. If we take the published reports of the operators of largest experience, like Mikulicz, Robson, Mayo, Moynihan and others, we find that both their immediate and remote results are far better than the results as given by internists. And yet, these surgeons of large and selected experience recognize the limitation, appreciate the failures and are as conservative in their judgment as one could wish. Through it all, and in spite of failures, the one great fact remains that ulcer of the stomach is more and more becoming a disease to be treated by the surgeon, not late but early; not as a last resort, but before the starvation, the long suffering from pain, dyspepsia and fermentation-absorption have reduced the patient until he is beyond surgical help; before he is anemic from persistent bleeding or peritonitic from culpable delay.

A discussion of the technique that so interests the surgical world has no place here. Each advance means more lives saved. Much of the complicated technique could be eliminated were it possible to give the surgeon his cases when he wishes and not when the physician is compelled. No one but a surgeon especially interested can keep pace with the phenomenal advance in this line, always for the better, within the last three years.

Compare the oft-quoted statement of Greenough and Joslin, that every other patient with gastric ulcer that one sees in the hospital is either to have a recurrence or never to be well again, with the results of the hundreds of cases reported by the various surgeons mentioned above. One must thereby be convinced of the value of surgery in this class of cases.

Another plea that I would make is for the internist in the present transitory stage of stomach surgery to found his pathological knowledge on living as well as upon postmortem dissection; in other words, let him see in the living that which the surgeon sees, and correct his views by these findings, not relying entirely on the limited knowledge obtained at the autopsy. Let me illustrate by a parallel example. A number of years ago, when there had been but one or two interval appendectomies in this neighborhood, I ventured to remove an appendix from a patient who had suffered for a long time from colics and indigestion. The appendix appeared normal, and one of our most eminent pathologists, who had obtained his knowledge entirely from postmortem findings, scored me severely for performing a meddlesome, unjustifiable operation. I will venture to say that within the last year there have been thousands of operations under similiar conditions, failure to perform which would now be considered unjustifiable.

Are the present methods of diagnosis by chemical analysis of any value? I am sure that at least three fourths of such diagnoses are of no practical value, when it comes to cases that would be classed as surgical by a surgeon. In my own limited experience the analyses have been interesting but much less reliable than general clinical data. The important thing for the patient and the surgeon is not to know that there is an ulcer, but to know that that ulcer is doing harm where it is situated; whether single or multiple (though that is of less importance); whether the ulcer symptoms may or may not be due to adhesions; what contractions there are consequent upon its healing; whether the base of the ulcer is already undergoing malignant degeneration; whether the ulcer is on one side or the other of the pylorus; whether the next hemorrhage may not be fatal, as I have seen so many times, comparatively, in ulcers medically treated. In other words, the internist may or may not be able to state that there is an ulcer; beyond that he cannot go. To determine whether there is a condition amenable to medical treatment he must experiment to a certain extent. If he succeeds, well and good; if he fails he must be willing to seek the co-oper-

ation of the surgeon, or better, he should have sought it early in order that both should study the case, and both should learn, each from the other's findings.

I will quote an oft-repeated statement by Mikulicz, who has had unusual and very great experience. He says: "The danger to life from gastric ulcer is at least not less but probably far greater than the danger of a complete modern operation." It is fair to say that gastric surgery has so rapidly progressed since that was written that the application is still more pertinent.

What cases are medical and what are surgical? No hard and fast line will be drawn for years to come. Many patients with first attacks, without serious hemorrhage, who can give up the time, and who realize the importance of prolonged rest, as so well emphasized by Shattuck, will recover permanently under medical treatment, but the following types are best considered as surgical: Probable cases of relapsing acute hemorrhage. Cases with hemorrhage if persistent and causing anemia. Perforation. Recurrent ulcer, pure and simple, attended with dyspepsia and starvation. Pyloric obstruction. Adhesions following ulcer or independent of it. Scar contraction of the body of the stomach. Some cases of intractable dyspepsia, perhaps originating in an ulcer, and for which no definite pathology is known.

Let us consider each of these types a little in detail. In relapsing hemorrhage various surgeons are already obtaining satisfactory results from a simple gastro-enterostomy.

In chronic hemorrhage, although all surgeons realize the imperfection in their results,— that is, occasional relapses, operative deaths, jejunal ulcers, etc.,— yet the benefits are so much better than from medical treatment, and the improvement in results is so steadily and surely advancing, that I have no hesitation in placing this type in the surgical list.

In perforation no one will deny the wisdom of early operation, and yet in this city there are physicians still who allow the first twelve hours to slip by before they summon surgical advice, unable or unwilling to make a diagnosis, and thus reduce the patient's chances of recovery from seventy in a hundred to practically nothing. Is there any valid excuse for this?

In cases of simple ulcer with dyspepsia and starvation, surgery has a wide field before it; far wider, I venture to predict, than medicine. Let me read that most graphic description of Moynihan's, published in the last issue of the BOSTON MEDICAL AND SURGICAL JOURNAL [June 4, 1903]: "There are few beings so abjectly miserable as those who are the victims of intractable dyspepsia. The meal time, which should be a delight, is a time of despair and foreboding. The keen relish of good food, which the man in physical health should appreciate, is a joy unknown or long forgotten to the dyspeptic. A patient who has misery written in every wrinkle of a thin and haggard face, who by reason of long suffering and bitter experience has felt compelled to abandon first one dish and then another, till fluids alone can be taken, and these not always with impunity, a patient, to say the truth, whose whole life becomes embittered by the pangs of a suffering which he must inflict upon himself, this patient will find if a gastro-enterostomy be done for the chronic ulcer, which is the source of all his trouble, that his return to health and appetite is at first almost beyond belief."

In cases of pyloric obstruction we have a purely mechanical problem with which to deal. No amount of medicine can overcome this condition, and no amount of argument by the internist can convince the surgeon that such cases are best treated medically.

Cases of adhesions from chronic ulcer, gall-bladder disease, appendicitis, etc., cannot be accurately diagnosticated without the aid of surgery, and very few of them can be relieved without operation.

Cases of beginning malignant degeneration cannot and probably never will be diagnosticated *in time* by the internist. What surgeon ventures to definitely say that a chronic mastitis is or is not starting a malignant focus? Even the pathologist may have to examine hundreds of sections. How much less likely are we able without operation to make a similar diagnosis in a chronic ulcer, situated we know not where in the stomach, of whose size and condition we are absolutely ignorant, and of whose actual presence we may be unaware!

In gastric neuroses of uncertain origin, but with a history of ulcer, many mistakes will be made by the surgeon. This class needs much study by specialists in all branches, but undoubtedly in a small proportion, on the theory of chances, surgery will be of some benefit.

In conclusion I would urge a more intimate co-operation of the physician and surgeon in the observation of patients with ulcer of the stomach. The surgeon must willingly grant that a majority of simple ulcers are best treated and cured by the internist, but on the other hand, the latter must as willingly consider surgical advice in the obstinate or serious types of cases, and learn in the living a pathology that it is impossible to learn in any other way.

DISCUSSION.

DR. E. P. JOSLIN of Boston: Six cases of ulcer of the stomach treated surgically have come under my observation. The reports of the cases are as follows:

CASE I. Miss E. F., forty-four, was seen March 7, 1902. Entered Boston City Hospital, Sept. 11, 1901. For the three years previous, dyspepsia. In March, 1900, vomited 6 oz. blood. Winter, 1900–1901, pain in epigastrium, which increased during the summer. Ewald test breakfast, September, 1901, showed 50 cc. or 0.18% hydrochloric acid. Hemin crystals.

Sept. 19, 1901. Gastro-enterostomy.

A pale, indurated, round area the size of a silver dollar was observed, which was situated midway on the lesser curvature upon the anterior wall.

Oct. 1. Phlebitis in left leg. Discharged Oct. 28.

March 7, 1902. Cramplike pain in region of stomach. Pale and rather thin. Fasting stomach showed lower bor-

der at navel and no tumor. It contained 12 cc. slightly greenish fluid. No free hydrochloric acid. Total acidity, 5. Mucus. Many leucocytes and a few red blood corpuscles. Died of cancer of the stomach, May, 1903.

CASE II. Miss K. M., fifty-one, was seen for the first time Oct. 21, 1902. Digestion never strong. In July, 1901, vomited, almost for the first time in her life, at midnight and again on the street five days later. Three days after this was strong enough to ride a bicycle from Buffalo to Niagara. Since this time has had vomiting spells every month until four weeks ago a vomiting spell lasting for two days. This was repeated four days and three days ago. In the last attack the quantity was two quarts and some of it was dark brown. Weight in 1893, 160, one year ago 143, now 123. Examination showed a fairly nourished woman with good color. Pulse 76.

Stomach — upper border 2 cm. below ensiform, lower at navel. No tenderness. Fasting stomach contained 240 cc. coffee ground material. Free hydrochloric acid present.

Oct. 22 to Nov. 18. Steady improvement, but on this day vomited. Free hydrochloric acid 0.1%. Total acidity 0.15%. The stomach was washed out Nov. 19, 20, 22, at which time the patient was taking but little under the normal quantity of food, but the second improvement did not continue. Several mild attacks of tetany occurred. On Nov. 29, Dr. Pfaff concurred in the diagnosis of ulcer and in advising operation. A gastro-enterostomy was done with an enterostomy by a Murphy button. At the operation the surgeon erroneously supposed that there was a cancer at the pylorus. Circular vomiting ensued and lasted till the death of the patient sixteen days later, Dec. 16, 1902. Tetany did not reappear after the operation.

Autopsy. — Dr. Hoag of the Boston City Hospital.

Gastro-intestinal tract. Mucosa of the posterior wall of the stomach is finely mottled by many conspicuous red points usually less than 1 mm. in diameter. Pylorus normal. One cm. below pylorus, upon the posterior surface of the duodeum, there lies an oval ulcer 1 cm. x 6 mm., entirely perforating the coats of the duodenum; margin, narrow, firm, inelastic, level and gray. The duodenum at this point is nearly occluded, admitting but the tip of the little finger. The margins of the ulceration are lightly attached to the anterior surface of the head of the pancreas so that no leakage occurs posteriorly.

The orifice of the gastro-jejunal anastomosis admits the tips of two fingers, and is bounded by a slightly elevated margin, unaccompanied by injection or other inflammatory sign. There is free communication between the two arms of the jejunal loop at the gastric opening. The second anastomosis, jejuno-jejunal, is perfectly patent and patulous, easily admitting the finger. Thus the anastomoses are perfect; no lack of infection is evident.

CASE III. Mr. M., sixty-two. First visit April 30, 1902. For thirty years pain in the epigastrium with heartburn. For one year has vomited frequently, and daily since April 26, two quarts at a time. Three weeks ago hemorrhage from the bowels sufficient to cause fainting. Alcoholic history. Vomitus — free hydrochloric acid 0.16%. Total acidity 0.32%. Sarcinæ. Examination showed fair color. Weight one year ago, 160; April 30, about 135. Lower border of stomach at navel.

May 12. No improvement under diet and lavage. Diagnosis — gastric ulcer and dilatation of the stomach. "Surgeon said in the consultation that he had never had a more favorable case for operation."

May 14. Operation.

May 15. Death with distended abdomen. Autopsy absolutely refused.

CASE IV. Miss S. D., twenty-seven, gave the following history on Oct. 24, 1902: Always had had stomach trouble. Vomiting from seven years to four years ago. March 18, 1898, vomited a hand basin full of blood, and this was repeated on the following day, notwithstanding that she had lived on milk for the preceding three months. July 6, 1898, perforation of the ulcer and emergency operation in the country, which was completed in August of the same year at the Boston City Hospital.

January, 1901, vomited one-half a cup full of blood, and on April 5, 1902, one half as much more, at both of which times she returned to the hospital for an ulcer cure. Appetite good. Weight, 1896, 98; April 27, 1903, 121. Occasional attacks of vomiting and pain after eating, similar to the pain before the perforation five years ago. Diet is extremely simple. At present is a telephone operator.

CASE V. Mr. H. D. S., thirty-one, consulted me March 4, 1901. Stomach always has been his weak point. In the early part of December, 1900, began to have faintness between meals with pain and hunger, and since that time has vomited on six occasions. Best weight, 157; weight to-day 151. Hemoglobin 80%. Pulse good. Splashing in abdomen easily obtained, but the stomach distended with air was ½ cm. above the navel though 3 cm. below the ensiform. Ewald test breakfast, 90 cc. free hydrochloric acid present, 10 cc. blood.

March 7. Entered the Deaconess Hospital and underwent a typical ulcer cure. During the first week several severe hemorrhages, but by April 20 had improved so much as to be allowed to convalesce out of town. Weight 118¼.

May 2. Hemoglobin 80%. Weight 134¼. Patient evidently was eating too much, though of simple food, and the diet was curtailed.

May 9. Weight 138.

May 11. Vomited blood and was sent to the Boston City Hospital, where he underwent a second ulcer cure, but at the end of a few weeks again vomited blood. Operation on June 15. Excision of an ulcer which partially narrowed the pylorus. Convalescence was slow but steady, and patient resumed work in nine months. June 24, 1903, reports himself very well.

CASE VI. Mr. A. H. H., fifty-nine, was seen May 30, 1903. His father was a chronic dyspeptic, vomited for fifty years and died at eighty. The patient has had for three years distress and gnawing pain in the stomach, which has been relieved by food and soda. In October, 1902, gave up work. Since October he has frequently vomited, and on a few occasions food which was eaten two days previously has been recognized in the vomitus. As a rule the vomiting has been voluntary. The patient has drunk large quantities of water and washed out the stomach in this manner. Involuntary vomiting has occurred only within a few days. On the morning of May 30 the patient vomited nearly two quarts of coffee-ground material, which contained free hydrochloric acid. Total acidity 74. No lactic acid. Sarcinæ present. Weight two and one-half years ago, 228; weight one year ago, 206; weight four months ago, 155; at present time about 135 pounds. Color, fair. Pulse 78 and of fair quality. No tumor felt in the stomach. Two days after the first hemorrhage another occurred. On the following day Dr. Pfaff, for whom I had made the single visit, saw the patient and advised operation, which was performed the next morning, June 3. An ulcer was found near the pylorus, which was nearly occluded by the inflamed mucous membrane. Gastro-enterostomy. To-day, June 9, uninterrupted recovery.[1]

SUMMARY AND RESULTS.

Case I. Hemorrhage. Gastro-enterostomy. Recovery from operation. Death twenty months later from cancer, which probably existed at the time of operation.

Case II. Hemorrhage and dilatation. Gastro-enterostomy. Entero-enterostomy. Death with circular vomiting sixteen days after operation.

Case III. Hemorrhage and dilatation. Gastro-enterostomy. Entero-enterostomy. Death within thirty-six hours.

Case IV. Operation for perforation. Recovery. Two subsequent attacks of hematemesis in following five years. Patient able to do light work, but has indigestion.

Case V. Hemorrhage and dilatation. Excision of ulcer. Recovery, and is well two years after operation

Case VI. Hemorrhage and dilatation. Gastro-enterostomy. Recovery. (Operation June 3, 1903.) Died July, 1903. Colloid cancer.

Excluding the first case, the mortality in these five operations is 40%. Of three patients who recovered from the operation, one has had two

[1] Patient died July, 1903. Colloid cancer of pylorus.

relapses in five years, one has remained well two years and one is doing well fourteen days after operation.

If ulcer of the stomach is to be operated upon successfully in Boston, a change must take place in present methods. There is an abundance of good surgeons, but few have had extensive experience in stomach surgery. In a ball game the members of a team always play their respective positions, but the surgical nines in our large hospitals play in any position that offers and the substitutes do the same. It is to be expected that each surgeon will have a number of failures while acquiring experience. When it is remembered that there are thirty or more surgeons, any one of whom may be called upon to operate upon ulcer of the stomach, the number of individuals destined to be offered up on the altar of experience becomes rather appalling. Until some agreement is reached whereby stomach surgery is limited to a few men, better statistics are not to be anticipated.

Dr. F. M. Sherman of Newton: I find myself, for the most part, in accord with the reader of the last paper. His advice that the physician and surgeon co-operate in the treatment and in the study of these cases seems to me timely, because I believe that the knowledge to be gained in the future through surgical experience will decide many of the questions now open concerning gastric ulcer.

The definite and positive opinions I have formed on the treatment of this affection are: *First.* That the majority of cases properly belong to the domain of medicine rather than of surgery. *Second.* That the best medical treatment is that long ago recommended by Wilson Fox and by Foster, which is rest in bed, no food by the mouth and rectal alimentation. If water is freely supplied most patients can stand a lot of starvation. In addition, water made alkaline with bicarbonate of soda may be administered, with the idea of diminishing the acidity of the gastric juice and irrigating the ulcer with a bland and slightly antiseptic fluid. Favorable results sometimes follow this treatment, even when imperfectly carried out; but the gravity of the affection is enough to warrant its rigid enforcement, and under it I think we may expect many patients to recover, and to recover more quickly and more easily than under any other treatment. *Third.* Nevertheless, in spite of any medical treatment, there will be a certain proportion of cases not benefited. These cases should be offered surgical treatment, not only because of the suffering, the disability and the ever-present dangers of hemorrhage and of perforation, but also because of the possible grave sequelæ, those, for example, resulting from perigastric adhesions, caused by a local peritonitis over the ulcer, or that very serious condition, cancerous change at the seat of the ulcer, which many believe to be common. *Fourth.* Cases of dangerous hemorrhage from gastric ulcer should have surgical treatment. *Fifth.* In case of perforation, surgical intervention is imperative, and the sooner the better. Early operation here offers a good chance for success.

Dr. J. H. Jackson of Fall River: I can add but little to the evidence as to the seriousness of the disease discussed, or to the methods of forwarding recovery. The papers have been wholly admirable and it is difficult to add to them. There may be some little things which may be of interest.

One thing I think has not been emphasized sufficiently, although it has been touched upon by four or five of the speakers and writers: The absolute necessity, in ulcer of the stomach, of rendering not only the stomach and bowels less acid but the condition of the blood less acid. Though we must consider the method of attack of acids upon the stomach, whether pepsin or hydrochloric acid or anything which attacks the stomach and causes the ulcer, these are secondary causes; behind them as a primary cause is lack of alkalinity of the blood, which promotes the condition favoring ulcer. Were the blood more alkaline, the acids would destroy the tissues less. Were it more in the condition of normal alkaline blood, it would not permit the peculiar provocative elements which attack the whole of the stomach; ruptured capillaries, embolism, infarctions and blood clot would be impossible. Hence the necessity of some addition to the blood to prevent the conditions which may induce the ulcer. If these conditions exist before the ulcer forms, they certainly exist in an accentuated degree after the formation of the ulcer. If acidity exists, why must we not overcome the tendency by methods that have been so well suggested in the discussions that have taken place? I feel sure that these things lie behind the condition which produces the ulcer. The ulcer is the cause of other troubles, coming out of its deep delving among the coats of the stomach, even puncturing them and causing adhesions.

Very little has been said about adhesions. Here comes in, if you have ascertained adhesions (as you may by various methods of physical examination) and a distended stomach, this question: What can we expect from medicine to establish a permanent cure? We may do much temporarily, and our patient recovers temporarily, with the remaining condition of a stomach which induces a recurrence of the trouble. Here comes in the need of the surgeon. These operations promise a great deal more in the future than is suggested by the past statistics. By all means, welcome the surgeon early in these cases.

As to the treatment, I have only a few words to say. All the things spoken of in the preceding papers and discussions need to be thought of in connection with it. The medical man is simply the one who meets the emergency for the time being, and if he is a wise man he will call in a surgeon, and he and the surgeon will lay their heads together, that they may accomplish the return of the patient to health.

In a distended stomach, with adhesions and an ulcer in it, with a band running around its

middle, making of the stomach an hour-glass or conical, with an ulcer an inch long,— if the pressure of food is aggravating this, what can pills and powders do that will permanently stop the hemorrhage? Welcome all efforts for cure of the disease by medicine, but by all means hand over the case in adhesions, stretching and dragging on the pylorus, or distention of the stomach, to the surgeon. Let us add to our medical treatment that of the surgeon

THE MEDICAL TREATMENT OF GASTRIC ULCER.[1]

BY HUBERT G. WILBUR, M.D., FALL RIVER.

PROPHYLAXIS.— From statistics obtained by Professor Welch, open ulcer of the stomach or cicatrix was found in 5% of persons dying from all causes. The average frequency of open ulcer was about 2% in persons dying from all causes. Judging from these and other postmortem records, gastric ulcer is of more frequent occurrence than is commonly supposed.

Now that so much of medical effort and energy is directed towards the prevention of disease, gastric ulcer should at least be guarded against in cases of anemia.

It has been proven by experiments on animals that when they were rendered anemic gastric ulcer developed from much slighter irritation and healed more slowly than when the blood was in its normal condition.

Traumatism and localized pressure may also cause ulcer. In chlorotic females it would be wise to regulate the diet to avoid very hot things, coarse foods, highly acid and highly seasoned foods; also avoid corsets and tight clothing.

Occupation has its effect in the causation of ulcer. Seamstresses, typewriters, tailors and clerks, who lean against the machine or desk, producing pressure against the stomach, are all liable to ulcer.

Welch reports a case of ulcer in a carpenter who leaned heavily against his chisel while at work; and another case in a shoemaker who cut leather while holding it firmly against his stomach.

Hyperacidity and hypersecretion of the gastric juices, especially if they be associated with altered blood condition, demand appropriate treatment, lest they too prove to be the forerunners of gastric ulcer.

TREATMENT.— The diagnosis of ulcer once established by local tenderness, pain, vomiting after taking food and hematemesis, the treatment indicated is: First, to secure rest in bed that the strength may be saved; second, to obtain absolute rest for the stomach until pain, vomiting and hemorrhage are relieved, relying on nourishment by bowel to maintain the vital force.

PAIN AND VOMITING.— Indigestion of food is usually attended with pain and vomiting. Food acts as an irritant to the sensory nerve at the abraded or ulcerated surface. Vomiting is also produced by the presence of food which the stomach is unable to take care of, and which it tries to eject. Food causes excessive secretion of the gastric juice, which in itself aggravates the ulcer; at the same time peristaltic action of the muscular coat is stimulated, thus increasing the liability to hemorrhage by the erosion of some of the small blood vessels. Hence pain, vomiting and hemorrhage demand absolute rest for the stomach for at least three or four days.

A case of chronic ulcer, under my observation for a period of eight years more or less, was of such peculiar interest that I may be pardoned if I briefly mention it here. The patient suffered from indigestion about all the time, but kept at his business. When I saw him at first I used lavage, with relief from pain and distress, and some improvement followed. After several months, however, the old symptoms returned, and he siphoned his stomach himself to get relief from pain and hyperacid condition. During the past three years the patient has had several attacks of vertigo, attended with a feeling of extreme weakness. Once I found him very pale, with small thready pulse, complaining of sickness of stomach, feeling very weak, and covered with a cold perspiration; this was followed by diarrhea, with dark, tarry stools.

During one of the acute attacks, in October, 1901, I sent him to Dr. H. F. Hewes of Boston. Dr. Hewes gave him an Ewald test breakfast, after washing his stomach out. After examination of the contents, Dr. Hewes reported: Acid in reaction; free hydrochloric acid present; also pepsin and renin. His diagnosis was gastroptosis, dilatation, decreased motor power, with a tendency to stasis. He suspected ulcer and possibly cance.

The patient continued in a fair condition of health, keeping nearly his usual weight, although the condition of his stomach allowed him to take very little nourishment. His appetite was very good; anything but the simplest food, however, was followed by great distress, pain and the formation of gases. His wife frequently siphoned out his stomach at night, because of severe pain, so that he might sleep.

In March of the present year, becoming perhaps a little more involved in business, and getting more than usually tired, his stomach refused to digest anything. The stomach was siphoned out repeatedly. At one time the result was a considerable amount of dark, granular fluid, coffee-ground in appearance; this was followed by dark, tarry stools.

I was called to see him at this time, and gave ergotole m. xxx to relieve the hemorrhage, with saline enemata and stimulants subcutaneously to sustain the pulse. On the following morning I gave a mild saline laxative to relieve acidity and cleanse the stomach of whatever of food or debris from the ulcer was there. Bismuth subnitrate in half-ounce doses stirred in a glass of warm water was given once daily, with some relief of pain and fermentation. No food was allowed by mouth for three or four days. Cracked ice was given to relieve thirst. Patient was fed by bowel. The nutrient enemata were at first egg and peptonized milk beaten well together, to which was added ʒ ii of claret. This was

[1] Read before The Massachusetts Medical Society, June 9, 1903.

given about three times in the twenty-four hours. This nourishment was not retained well, and caused a good deal of distress and gas, and the subsequent cleansing enema showed that it was not well absorbed. Predigested beef and Bovinine were tried, but they did not seem to be well taken up by the bowel. The patient became weaker day by day, he developed fever and mild delirium; nothing was retained, whether taken by mouth or by bowel, and he died after ten days' sickness.

A postmortem was obtained. A large ulcer, with shelving edges, about one and a quarter inches in diameter, was found near the pylorus. About one inch in towards the pylorus a scar was found, about one inch in length. Dr. Mallory examined the stomach, and pronounced it a case of simple ulcer.

If thirst be a troublesome symptom in these cases, small pieces of cracked ice may be tried or an enema of water be given. Violent pain and continued vomiting call for external applications of laudanum fomentations. A mixture of chloroform ʒ i, alcohol ʒ iii, applied on flannel will relieve pain. In obstinate vomiting I have used gr. 80 of sodium bromide with ext. cannabis indica gr. ½ by enema, with excellent results. This failing, opium by suppository or morphin subcutaneously will give relief, but they should not be tried until other remedies have failed.

FEEDING BY THE BOWEL.— In most cases rectal feeding is disagreeable to the patient and liable to be irritating at first to the bowel; hence it is best to begin with comparatively small doses, and at intervals of about eight hours. The tendency has been, I think, to give the nourishment by bowel too frequently. The usual enema is absorbed slowly; hence a sufficiently long interval between the feedings is desirable, until we establish tolerance on the part of the colon. Once the bowel is educated up to taking food at regular intervals, then we can feed the patient for at least ten days or two weeks, until the more aggravated stomach symptoms have subsided, when we can gradually resume regular feeding by mouth. In all cases the rectum must be cleansed with one pint or more of warm salt water about an hour before each enema. We can then determine to what extent the food has been absorbed. If we find that it has not been well taken up by the bowel, it will be advisable to change to a more simple form of nourishment.

The anemic condition must be remedied by iron in some form. The ideal nutrient, then, to sustain strength and renew the impoverished blood would seem to be blood itself. We know from experiment that defibrinated blood is wholly absorbed by the bowel when given in small amounts, ʒ 5 or 6 at a time. There may be some difficulty in obtaining blood, since it is not so readily accessible as the other foods.

Stewart's formula is one that should meet the condition; namely, a heaping teaspoonful of somatose is dissolved in as little water as possible; two eggs are thoroughly whipped with it; and ʒ 4 of peptonized milk gruel added to it; the whole not to exceed ʒ 8. Papain is given for the digestion of the egg. If the enema is well borne, he adds some form of the albuminate of iron (preferably Dree's), ʒ ½ to 1.

To combat anemia and improve the general condition, Ewald used ʒ j of a 3% solution of ferri chlorid in a wineglassful of egg water (one part white of egg, two parts of water), taken through a glass tube to protect the teeth. He maintains that chloride of iron is one of the best and most easily assimilable preparations that there are. With the iron he gives arsenious acid gr. 1-30 in pill form; this treatment he continues for months.

Since rectal feeding is not sufficient to sustain strength very long, we should try feeding by mouth as soon as we think it safe to do so. After two or three days' rest the stomach will admit of gradual resumption of food. Begin with very small doses of milk and lime water, a teaspoonful at a time; liquids in a predigested form; peptonized milk gruel; matzoon; and milk thickened with partially digested starchy foods, such as Nestle's, Mellin's, Malted Milk or Imperial Granum, to prevent the congulation of the milk. If foods prepared with milk disagree, give beef juice in teaspoonful doses, either peptonized or pancreatized, or egg albumin beaten and prepared with sherry wine.

If a bland diet is tolerated, we gradually add to it broths, eggs, light puddings, sweetbreads, minced chicken and finely scraped beef, being careful to eliminate all foods likely to irritate the stomach, such as brown bread, oatmeal, coarse vegetables and fruit. As the gastric symptoms disappear we may give toast, rusks, rare roast beef and beefsteak. Any serious departure from a strict diet carefully laid down may bring about a return of the old symptoms.

Hemorrhage occurs in about 50% of all cases. In repeated and profuse hemorrhage Dreschfeld advises turpentine and considers it to give great relief. He administers it in capsules, or in emulsion ʒ ii thoroughly beaten up with the white of one egg. The dose is m.xx or xxx of the mixture.

He cites several cases of hematemesis in which the patient was pulseless and blanched to an extreme degree, in which ice, gallic acid, ergotin injections and other styptics were tried in vain, and in which the first dose of turpentine completely stopped the hemorrhage. It is well borne by the stomach.

In case of hemorrhage with symptoms of collapse, flood the colon with hot salt solution, ʒ 1 to the pint, and give digitalin gr. 1-30 and strychnia gr. 1-30 subcutaneously.

In case of perforation radical surgical interference is at once demanded. If the surgeon is not at hand, give morphia subcutaneously to quiet peristalsis and relieve pain, and brandy and coffee by enema to sustain the heart.

Medical Progress.

REPORT ON OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

(Concluded from No. 7, page 181.)

THE SURGICAL TREATMENT OF PUERPERAL PYEMIA.

MICHELS[16] in his contribution limits pyemia to that form of puerperal infection which is propagated by way of the venous circulation, and is characterized by rigors with high rises of temperature, and usually leads after an acute course to a fatal termination by septic emboli in the lungs or other organs.

He cites five cases operated and reported by Trendelenburg, four of which proved fatal, and one less acute, which recovered after ligature of the right internal iliac and right ovarian veins.

Michels then reports a case of puerperal pyemia in his hospital practice, in which through the usual methods of treatment the local conditions had been greatly improved, the uterus had contracted and the fetid uterine discharge ceased, but the general condition continued very alarming, with very high temperature and repeated rigors. A distinct fullness was noted in the left inguinal region, which suggested a thrombosis of the ovarian vein. Accordingly an operation was performed, and the ovarian vein, which was thickened and dilated, was ligated in two places about half an inch below the renal vein, and then divided between the ligatures. The vein was then exposed to its point of exit from the broad ligament, slit open and a fetid mass of softened thrombus with small accumulations of pus removed. The effect of the operation was surprising — no more rigors occurred, the general condition improved rapidly and, although the wound healed slowly, it healed completely, and the patient left the hospital strong and well.

RECURRENT ABORTION.

Taylor[17] says that the usual term of "habitual" abortion is objectional, as the theory that the uterus can without any exciting causes form a habit of aborting at a certain period is only an idea, and that there is no longer any real justification for its continuance. He includes under the title of recurrent abortion only those cases where from the beginning or from some definite epoch the patient has aborted with each succeeding pregnancy.

[16] Lancet, January, 1903, p. 1025.
[17] Brit. Med. Journ., January, 1903, p. 835.

Of the rare causes of recurrent abortion a few are due to intraperitoneal adhesions, to chronic kidney disease with albuminuria and to deep lacerations of the cervix. When all these rarer causes of recurrent abortion are accounted for, and when syphilis can be rigidly excluded, there still remains a definite group of cases of very nearly equal importance to that belonging to syphilis. The distinguishing features which bind these cases together are (1) indications of a low vitality on the part of the mother or father, or both; (2) a strumous family history; and (3) what he calls the remarkable result of an essentially antistrumous treatment when carried on for a long period of time or throughout the whole of the pregnancy. Twelve of the latter type of cases are tabulated. In syphilitic cases each succeeding abortion, if the patient's general condition remains satisfactory, tends to occur at a later period, until the pregnancy goes to term. At this stage dead children are usually born, but finally living children may be expected. In the strumous class, unless something is done to improve the general health, each abortion tends to further weaken the patient, each succeeding abortion tends to occur at an earlier period, and finally in some untreated cases the power of conception is lost. In the majority of these cases there is a fairly clear family history of strumous disease.

He attaches chief importance to the defective vitality of the mother in these cases of recurrent abortion, and everything which tends to improve the general health of the mother and child is of the utmost importance in successful treatment.

PELVIC LESIONS FOLLOWING LABOR.

Hill,[18] in discussing the pelvic lesions following labor, says that in the occipito-anterior position it is of the very greatest importance that the nape of the neck be well under the pubes before the forehead is allowed to glide over the perineum. To insure this he often makes pressure on the perineum between the anus and coccyx. He would abstain from all rectal manipulations for this purpose, as he should not only fear injury to this organ, but also septic infection. At times he would advise to push the soft parts of the mother, anterior to the head, back under the pubes and thus favor the birth of the occiput. The patient should be directed to cease all voluntary efforts at expulsion. This is much helped by talking sharply to the patient and by delivery in the lateral-prone position, as the activity of the abdominal muscles is thereby lessened to a marked degree. Elevation of the lumbar region, when the patient is on her back, so as to increase the inclination of the pelvis, is strongly recommended by that master of obstetrics, Professor Schultze of Jena. The occipito-posterior position presents almost unlimited chances for destruction of the soft parts at the outlet. The careful obstetrician can, in a majority of cases, avoid this position by early assistance, rotating the head so that the occiput

[18] Am. Journ. Obst., January, 1903, pp. 81, 82.

will turn forward. Slow dilatation is of immense importance in avoiding perineal as well as cervical lacerations.

In speaking further of the avoidance of injuries, he refers to those extensive lacerations of the cervix occurring from application of forceps with an undilated and non-retracted cervix. He says we must first bear in mind that the operation is an exceedingly serious one, and that the avoidance of the injury lies in the fact that it must never be undertaken unless the indication is a most important one. When we are forced to it the prognosis should be a guarded one and every means exhausted to obtain a normal dilatation and retraction. At times it will be wise to incise the anterior or lateral lips of the cervix.

In speaking of the results of birth injuries, he refers to the immediate and the remote. The immediate is summed up by the likelihood of sepsis. The remote results are of the greatest importance and deserve our closest study. Too much stress cannot be laid upon the seriousness of some of these injuries, especially those produced by the forceps on the unretracted cervix. Some of the patients remain invalids for years; others never regain their health. The latter cases are those where there is great destruction of the cellular tissue in the base of the broad ligament and beneath the vagina. He insists that this condition is much more frequent than is ordinarily supposed and very serious to the well-being of the individual.

MECHANISM AND INSTRUMENTAL DELIVERY IN TRANSVERSE POSITIONS OF THE HEAD AT THE BRIM.

Gillespie[19] remarks on the great difference between low forceps and high forceps operations. Instrumental assistance with the head at the inferior strait is a safe procedure for any one who possesses reasonable operative judgment; forceps at the superior strait requires as much judgment for its proper performance as any obstetrical or gynecological operation with which he is acquainted. The intelligent use of forceps at the superior strait presupposes an exact knowledge of mechanical relations of the head to the pelvis and a careful differentiation of the cause of delay. If we may judge from text-book descriptions of the operation, this exact knowledge is seldom possessed, and the advantages of a differentiation of the cause of delay are frequently not appreciated. The rule generally followed of applying the blades to the sides of the pelvis, without regard to the diameter of the head grasped, is in his opinion as unscientific as would be an unvarying technique in hysterectomy for fibroids regardless of the shape and direction of the growth. Many have such a wholesome fear of the high forceps operation that they invariably perform version when the head is impacted in the brim. He says we cannot do better in the beginning than is stated by Robert Barnes: "In proportion as the head is low in the pelvis, high in the pelvis or above the brim, the necessity, utility and safety of forceps diminish."

Gillespie states that there are many conditions which render it advisable or necessary to apply forceps at the superior strait. He considers those conditions only which cause transverse positions of the vertex, such as flat pelvis. In these cases the head is not only transverse in the brim, but approaches that side of the pelvis toward which the occiput is directed, leaving the other side comparatively free. As the concave edge of the blade must be turned toward the occiput, it follows that the blade, which must find lodgment under the pubes, passes upon this comparatively empty side. There is, therefore, much less likelihood of the blade being nipped and held firmly between the side of the pelvis and the head than in the more normal oblique positions in which there is disproportion. So long as the sagittal suture is drawing nearer the pubes we should keep hands off; but when it begins to recede, showing that the point of contact with the promontory has become fixed, assistance comes within the range of possibility. Gillespie describes the method of applying the blade under these circumstances. A frequent cause of transverse position at the brim is an increased tilting of the brim as a result of excess of the sacrovertebral angle. Lack of flexion is another element in the problem of posterior rotation, which is intimately associated with abridgment of the conjugate. Three cases are reported.

PUBIOTOMY — LATERAL SECTION OF THE PUBIC BONE.

Gigli[20] has proposed and performed lateral section of the pubic bone by means of his chain saw, in place of the usual operation for symphyseotomy, in which the ligaments of the pubic joint are severed for obstructed labor. He has performed the operation several times, and the patients have all recovered with good results. He claims there is less hemorrhage, and the union of the bones is firmer and surer than at the joint, and that it is well known that many patients have loose pelvic articulations after section of the symphysis.

A number of cases of lateral section have been reported, two by Pistalozza,[21] who favors the new procedure. Two cases are also reported by Van de Velde,[22] who also warmly advocates the operation.

An incision is made from the left pubic spine downwards and inwards to the outer border of the labia majora, at the level of the vestibule. When the bone is reached, a cord is passed round it by means of a specially curved needle, and by this means a Gigli saw is drawn into place, and the pubis divided. A separation of the fragments to the length of about 5 cm. is obtained. After the child has been extracted, the periosteum is sutured with strong silk, and the lower

[19] Am. Journ. Obst., January, 1903.

[20] Zeitschr. f. Geburt. u. Gynäk., No. 4, 1903.
[21] Centralbl. f. Gynäk., No. 37, 1902.
[22] Peterson: Obstetrics, 1903.

end of the wound is left open to allow for drainage. A pelvic bandage should always be employed. The stitches can be removed on the seventh day. Van de Velde prefers pubiotomy to symphyseotomy for the following reasons: (1) The wound is not near bladder or urethra. (2) The soft parts round the divided bone are thicker than round the symphysis, so a laceration extending from the wound to the vagina is less likely to occur. (3) The distance of the operation site from the clitoris lessens the risk of hemorrhage. (4) The adductor longus and gracilis muscles prevent too great separation of the fragments. As a result, healing is more rapid and the chances of infection are less.

TREATMENT OF PLACENTA PREVIA.

De Lee,[23] basing his judgment upon thirty cases of placenta previa which he has had, says he feels justified in making the following statements:

(I) A woman with placenta previa ought not to die, except in rare instances, such as air embolism or the hemorrhagic diathesis.

(II) A case of placenta previa should not be half-heartedly treated. If the child is viable, labor should be induced. When the hemorrhage is very moderate one may wait, provided that the patient remains in bed and is in a well-appointed hospital.

(III) No one method of treatment will meet all cases. The accoucheur should have all known measures at his command.

(IV) The young practitioner should follow Schroeder, who says: "That accoucheur will have the best results in placenta previa who has the least regard for the child."

Medical writers whose words are read by the general profession, and medical teachers whose precepts are followed by, at first, blind and inexperienced hands, should be careful what they recommend for universal practice. One should recommend to those of less skill only such measures as in such hands may lead to the best results. The man with his first case of placenta previa, therefore, should direct his efforts to saving the mother. Later on, when the parturient canal is no longer a blank space, when dexterity has been acquired and, rarest and most difficult of attainment of all, obstetric judgment has become a possession of the accoucheur, he may make an earnest effort to improve the mortality of the child.

(V) Placenta previa is a formidable condition, more formidable than most laparotomies, and to insure the best results the patient should be in a well-equipped obstetric operating room.

(VI) The best way to induce labor is to puncture the bag of waters and to put a colpeurynter in the uterus, resting on the placenta and pressing this against the cervix, and then to put traction on the tube.

(VII) After labor is inaugurated, or should the case be received when it is already begun and hemorrhage more or less severe has occurred, the treatment should be pursued with vigor, and the doctor must not leave his patient till she is delivered and all danger is past.

(VIII) The treatment, then, is as follows:

The objects are: (1) to stop the hemorrhage; (2) to empty the uterus; (3) to secure contraction and retraction of the uterus; and (4) to ensure complete hemostasis. The state of the cervix and the degree of hemorrhage indicate the course to pursue.

INTRAVENOUS INJECTIONS OF FORMALDEHYDE FOR PUERPERAL SEPSIS.

Much has been printed during the past six months on the subject of intravascular antisepsis, a large portion of which has no doubt been inspired by the publication of Barrows' case of puerperal sepsis, recovery of a very sick patient following the intravenous injection of 1,250 cc. of a 1 to 5,000 solution of formalin in normal salt solution.

The intravenous injection of drugs and even of formalin solutions for their antiseptic action is by no means a new suggestion or procedure, although the publication of Barrows' case, appearing as it did first in the lay press, produced rather an unusual amount of interest.

If Barrows' case had been published in the usual manner in a medical journal, without having first been widely advertised in the daily press, it is highly probable that it would have created no unusual interest or comment. This is true because cases quite as much *in extremis* as Barrows' have been known to recover under simple supportive treatment, or after the injection of normal salt solution, the use of antistreptococcus serum, Crede's ointment and various other forms of treatment which have from time to time been lauded as specifics for septicemia, but all of which have subsequently proved disappointing.

It is perhaps too early to pronounce at the present time a final verdict on the use of formalin as described, but what clinical evidence we possess points to the conclusion that the favorable result in Barrows' case may have been merely coincident or may have been due to several other factors.

In the *Lancet* of Jan. 10, 1903, three weeks before the publication of Barrows, Fortesque-Brickdale, in a paper on "Intravascular Antisepsis," from the Bacteriological Department of the Jenner Institute of Preventive Medicine, says that the idea that drugs might advantageously be administered by direct injection into the circulation was first started by an English mathematician, and had its latest exponent in an Italian cabinet minister. Sir Christopher Wren in 1656 was the first to carry out the experiment, and the medical profession has coquetted with the method ever since, exaggerated enthusiasm for it alternating with absolute neglect. He gives the results of a number of laboratory experiments upon animals in the injection of various drugs, and in conclusion says that at present there is no experimental evidence which would warrant the

assumption that the course of a septicemia in animals can be influenced favorably by the intravenous injection of antiseptic substances, and that in view of his results and those obtained by former investigators, it seems useless to continue trying to apply clinically a method which, while not free from special dangers, is at present unsupported by any experimental evidence either as to its present advantages or future prospects.

Park and Payne in the *Medical News* for April 4, 1903, report the results of their experiments on the intravenous injection of dilute formalin solution in septicemic rabbits. Their work was done at the Research Laboratory in New York after the report of Dr. Barrows' case. Their results agree with those of Fortesque-Brickdale quoted earlier, and their conclusions are essentially the same with regard to the dangers and inutility of formalin injections, while they also demonstrated that even after large doses of formalin the streptococci can still increase in the blood.

Barrows[24] in a recent communication defends the use of intravascular antiseptics, claiming that experiments made on rabbits with unfavorable results do not necessarily represent the conditions in the human subject. He reports a number of cases successfully treated. He says he does not wish to stand as a champion for the single chemical element which has given such satisfaction in his hands, but he believes that from a study of his cases other lines of treatment in this direction may be stimulated.

Reports of Societies.

FIFTY-FIRST ANNUAL MEETING OF THE MAINE MEDICAL ASSOCIATION.

THE fifty-first annual meeting and semi-centenary celebration of the Maine Medical Association was held in Portland, June 3, 4 and 5, 1903. On the recommendation of the president for the preceding year, Dr. F. H. Gerrish, the exercises throughout partook of a special character. The only papers presented were of an historical character, but the reports of special committees were of unusual interest and called out a very free discussion.

FIRST DAY — MORNING SESSION.

The meeting was called to order by the president, DR. HIRAM HUNT of Greenville, at 10.30 o'clock.

DR. AUGUSTUS THAYER of Portland read his report as treasurer, showing a balance of $2,378.91, notwithstanding the fact that $1,000 had been appropriated during the year for the proposed Maine Sanatorium for Consumptives.

DR. ADDISON S. THAYER presented the report of the Committee on Change of Laws Governing the Commitment and Discharge of the Insane.

[24] N. Y. Med. Journ., Jan. 31, 1903, p. 177; *ibid.*, July 4 and 11, 1903, pp. 5 and 65.

"According to present law in Maine, a person who desires the commitment of another person alleged to be insane, must sign in writing a formal complaint. A copy of this complaint must be given in hand to the person alleged to be insane. The alleged insane person must also be notified of the time and place of a hearing, and that he has the right and will be given an opportunity then and there to be heard."

Judge Walton in 1888 in the Knox County Court ruled:

"When an adjudication is to be made which will seriously affect the rights of a person, he should be notified and have an opportunity to be heard." "We do not find any decision in this state or Massachusetts which holds directly and positively that such a notice is necessary."

To avert doubt as to the legality of future commitments the last legislature amended the statutes so that they conform to the principles laid down by Judge Walton.

The committee expressed the belief that the commitment of persons who are not insane rarely occurs. They advised firmness on the part of hospital authorities to prevent the premature discharge of insane patients.

DR. B. T. SANBORN, superintendent of the Maine Insane Hospital, in discussing the report said that he wished to call attention to a new law passed by the legislature relative to the admission of patients to an insane hospital.

There must be *legal* evidence that two reputable physicians have testified to the fact of insanity, and no person shall be deprived of his liberty without legal commitment. Regarding the premature discharge of insane patients, Dr. Sanborn spoke of the formerly overcrowded condition of the Maine Insane Hospital and the necessity of always receiving and retaining the more dangerously insane, and this had made it necessary to discharge others whose condition was not so bad.

It was voted that the committee be retained to secure suitable laws, if possible, from the next legislature.

The Committee on Legislation Regarding Victims of Drug Habits reported progress, and was retained for another year.

In discussing the subject DR. W. L. HUNT said that he would like to have the insane law stretched over the inebriate, somewhat similar to the Massachusetts law, and spoke of the difficulty of committing an individual insane through drink. He believed that such patients should be admitted to the insane hospital.

DR. F. H. GERRISH of Portland suggested that the committee endeavor to obtain from the next legislature an adequate and proper law.

DR. B. T. SANBORN spoke of the difficulties attending voluntary commitment, and expressed his opinion that an insane hospital was not the proper place for inebriates and drug habitués. He expressed the hope that a suitable institution for the care of such patients might be established by the state.

DR. S. C. GORDON favored a law enabling a

drunkard to be confined in an insane hospital or similar institution.

DR. F. H. GERRISH of Portland said: Patients addicted to the use of drugs have their moral sense completely blunted, and it is extremely difficult to manage such cases. I believe that a law should be framed by which a man might voluntarily relinquish his liberty for a stated period. In this way the physician could control his patient and not be liable for false imprisonment.

DR. WALTER ELWELL, superintendent of the National Soldiers' Home at Togus, endorsed Dr. Gerrish's views.

DR. B. B. FOSTER of Portland spoke of the necessity of absolute control by the physician of inebriates and drug habitués, but believed that it would be extremely difficult to secure such a law.

It was voted that the committee be continued to the next annual meeting.

DR. G. M. ELLIOTT of Brunswick presented the report of the Committee on the Expediency of Adding Venereal Diseases to the List of those reported to the Board of Health.

The committee proposed a legislative act:

(1) To add syphilis and gonorrhea to the list of diseases to be reported.

(2) To provide free treatment for patients with these diseases.

(3) To restrict the marriage of such as have a communicable form of either disease.

(4) To penalize the wilful spreading of either of these diseases.

(5) To have the State Board of Health prepare a circular such as is now prepared for some of the other diseases, and require each physician to give the patient a copy in each newly seen case, and certify to the local board of health that such patient has been given a copy.

DR. F. H. GERRISH said: This deals with an important subject, though an old one. Twenty-five years ago I made similar suggestions regarding prostitution, and brought the subject to notice again a year ago, and this matter has been conducted with the utmost deliberation. We should add gonorrhea and syphilis to the list of reportable contagious diseases. An effort to obtain the venereal morbidity in New York showed 225,000 cases as against 41,145 reported diseases in one year. In our meeting last year Dr. Oakes referred to gonorrhea as "this most hideous disease," and yet spoke against securing legislation. Some of the objections urged against the passage of this law are: That it could not go through the legislature on account of the sympathy of members who may have been afflicted; that it would drive these cases to druggists and quacks for treatment; that doctors would not report cases since cases of tuberculosis are not reported; and that it is bad to have a law on the books that is not enforced.

The law against fornication is not enforced, and the law against theft only brings to justice a fractional part of the offenders; but they should remain laws to apply when possible.

It is said that to report these cases would be a violation of professional secrecy; but, if the law compelled, there would be no ground for complaint. The proposed law would have an educational value, as the law against spitting in public places has a salutary effect. The law does not contemplate isolation and is for the advancement of public welfare. We do not hesitate to enforce the law in scarlet fever; why should we in these diseases? The medical profession needs education on these points.

DR. GUSTAV PUDOR advised licensing brothels, as the plan had worked well in Berlin and afforded protection from contagion. He believed that pupils in the upper classes of grammar schools should be instructed on the dangers of such matters.

DR. B. B. FOSTER said that in his judgment the proposed law could not be enforced if adopted. It would certainly drive the treatment of these diseases into the hands of the druggists. He spoke of the great prevalence of gonorrhea and syphilis, and showed that the former was much the more serious disease. He believed that young men should be educated in these matters, and favored legislation that would limit the treatment of these diseases to competent physicians. He estimated that 70% of the male population over the age of thirty-five had had gonorrhea.

DR. WALTER B. ELWELL of Togus said: I think that Dr. Foster has overestimated the extent of venereal diseases. I have examined thousands of men and believe that, counting both syphilis and gonorrhea among old soldiers, 52% is a high estimate.

DR. JOHN F. THOMPSON, Portland, said: The administration of drugs by pharmacists is to be especially condemned. Patients of this class should be treated by qualified physicians and specialists rather than by general practitioners. The proposed law, I believe, is too radical; and I hold that we must approach the desired end gradually. I do not believe that the simple reporting of cases will do any good.

It was voted that the committee be retained for another year and that it appoint a delegate or delegates to the Congress of Venereal Diseases at St. Louis in 1904.

FIRST DAY — AFTERNOON SESSION.

The delegates to other societies and institutions presented their various reports, after which DR. HIRAM HUNT of Greenville delivered the

PRESIDENT'S ADDRESS.

Dr. Hunt called attention to the special character of this meeting, and said: "As it is fitting that everything connected with the association should be reviewed, so it will be profitable to study all things medical, to note the progress of surgery since the organization of this association and before, to note, also, the progress in every branch of medicine." He spoke of the great value of medical societies, with special

reference to their contributions to education and mutual professional improvement. He called attention to the various legislative acts that the Maine Medical Association had been instrumental in securing. Regarding county societies, he said: "During the past year one condition has been forcibly brought to my attention, and that is the absence of union between this association and the county societies. If a satisfactory plan could be adopted which would unite this association and the county societies, it would probably result in a large membership in both, a better organization of the profession of the state and be mutually advantageous.

"The American Medical Association plan for organizing the profession has been adopted in eighteen states. I am not convinced that this plan is advisable for our association, but any plan, especially one recommended by the American Medical Association, with whom our association has always been affiliated, should have careful and respectful consideration. I suggest that a committee be appointed to consider the plan advised by the American Medical Association, to report at the next annual meeting."

DR. CHARLES O. HUNT of Portland then read a paper on

THE HISTORY OF THE ASSOCIATION.

The association gave Dr. Hunt a vote of thanks and also voted that the paper be published in the Transactions.

SECOND DAY.

Instead of a business session in the morning, an exhibition of Curiosities and Anomalies of Medicine was held in the amphitheater of the Maine General Hospital. Physicians from all over the state brought patients afflicted with rare diseases and unusual deformities. The list included many congenital malformations, some of the rarer diseases of nutrition and a collection of remarkable skin diseases.

The following cases were among those exhibited: General anchylosis, cretinism, congenital absence of fingers, fibroma of nose involving entire face, congenital dislocation of hips, acanthosis nigracans, ichthyosis, psoriasis, general eczema and sycosis.

The exhibition, which was under the charge of Dr. Frederic H. Gerrish for the Business Committee, lasted over two hours, and was greatly appreciated.

SECOND DAY — AFTERNOON SESSION.

The president introduced as delegate from the New York State Medical Association, its president, DR. FREDERICK HOLME WIGGIN, who made a brief address referring to the work of his association.

DR. T. F. GARTLAND of the Vermont Medical Association was introduced as its delegate.

The Committee on the President's Address recommended that "a committee of organization be appointed to act on the plan proposed by the American Medical Association." By vote of the association, such a committee was appointed.

The Board of Censors advised the management of the medical exhibit by the association, or that investigation be made regarding its control. A committee was appointed for this purpose.

DR. J. L. M. WILLIS of Eliot read a paper on

THE HISTORY OF MEDICINE IN MAINE PRIOR TO 1853.

DR. WILLIS B. MOULTON of Portland read a paper on the

HISTORY OF MEDICINE IN MAINE OUTSIDE THE ASSOCIATION SINCE 1853.

Both papers were referred to the committee for publication.

DR. CHARLES D. SMITH spoke in favor of a national act of incorporation of the American Medical Association, and it was voted that the delegate favor this act.

DR. S. H. WEEKS spoke for the Maine Sanatorium Association, reported progress and called for a motion that the association appropriate fifty dollars a year for the benefit of the institution. The motion was put and called out some discussion, as the association at the previous annual meeting had donated one thousand dollars. It was finally voted that fifty dollars be appropriated annually for ten years.

The president called attention to the presence of two of the charter members, and introduced DR. ALONZO GARCELON of Lewiston and DR. CYRUS KINDRICK of Litchfield Corner.

The officers for the next year are: President, Dr. Augustus S. Thayer, Portland; Secretary, Dr. Walter E. Tobie, Portland; Treasurer, Dr. Arthur S. Gilson, Portland.

In the evening a banquet was held at the Lafayette Hotel. There were present two hundred members and guests of the association.

The third day, June 5, was devoted to a sail in Casco Bay and a shore dinner on Long Island. The physicians and their wives, to the number of two hundred, took part in this event, which concluded the program. A special effort had been made to have as many physicians as possible attend the meeting accompanied by ladies. The visiting ladies received every possible attention. Many were entertained by the wives of the Portland doctors, and a committee of ladies called on all visitors whose addresses could be obtained. Mrs. John F. Thompson held a reception on Wednesday afternoon. Thursday morning the ladies enjoyed a trolley ride about Portland, finishing with a lunch at Riverton.

On the evening of June 8 the association had reserved for them two hundred seats at the Jefferson Theater, and with their ladies attended a performance of "The Conquerors."

THE BOSTON

Medical and Surgical Journal

THURSDAY, AUGUST 20, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

PROGRESS IN THE TREATMENT OF THE DEPENDENT POOR.

A FEW days since an editorial appeared in the Boston *Herald* calling attention to the improved public spirit prevailing in New York toward its dependent poor, commonly known as paupers. The term "pauper" has acquired a most unenviable reputation, and the first step apparently in an amelioration of the condition and the elevation of the self-respect of these dependent persons is to change this term to one perhaps having a similar significance, but less unpleasant associations. In New York the word "ward" has been substituted, and possibly, owing to this fact, the dependent class is undergoing a distinct change for the better. A so-called farm colony has been established on Staten Island, and in the course of time an administration building, chapel and an adequate number of cottages are to be erected for the comfortable housing of the poor. Aged married couples are to be permitted to live together until one or the other dies, whereas in former times such persons, having become dependent upon the city, were separated. By these general means it is suggested that a beginning may be made toward the realization of Mr. Jacob Riis' hope that ultimately the charitable institutions on the East River Islands may be removed to make way for island parks for the poor.

A similar idea to that described above had been suggested also for Boston, as may be seen by reference to the report of 1902 of the pauper institutions' trustees, wherein the following statement is made:

> The difficulties of classifying an almshouse population seem to be inherent where so many feeble persons are housed, fed and cared for together. A plan which has been suggested, and which might tend to obviate some of the disadvantages of the congregate system of housing, would be to provide a number of cottage almshouses, with separate establishments, where each household could fulfill the duties of caring for the building and adjacent grounds without requiring so much assistance from officers as is necessary in a large institution.

The *Transcript*, in an editorial, comments on this suggestion, and accounts for the fact that the change has never been carried out in Boston owing probably to the fact that the institutions are established on a different basis, and that such a change would involve a very considerable expense. It is, however, worthy of mention that the plan which has apparently been carried to a successful issue in New York, had already been suggested for the poor of Boston.

It is in general of very great interest to note from time to time the change in public sentiment which is going on in regard to those who through misfortune or illness, or even through their own fault, are forced into public institutions. We have frequently enough commented upon the change of the word "asylum" to "hospital," and we may look forward with confidence to a gradual awakening of public opinion to the injustice of the situation which condemns persons suffering from chronic disease to the declaration of pauperism before they may be cared for by the city or state of which they may chance to be citizens. The distinction should most certainly be drawn between that class in the community which is able-bodied and which simply, through lack of initiative or viciousness, refuses to work and that increasingly large class of individuals who through illness is condemned to a life of idleness. These latter should be forthwith regarded as sick persons, and any social stigma attaching to them should be removed, so long as they remain in the condition of invalids. In time, no doubt, the idea of hospitals for chronic disease will gain weight and strength sufficient to set right many of the injustices which now prevail.

ETIOLOGY OF YELLOW FEVER.

LITERATURE on yellow fever is becoming abundant. We have before us one of the most recent contributions to the general subject, being the Report of Working Party No. 1 of the Yellow Fever Institute, published under the auspices of the Treasury Department of the Government. This party consisted of Assistant Surgeon Herman B. Parker and Acting Assistant Surgeons George E. Beyer and O. L. Pothier. The work was

undertaken at Vera Cruz, Mexico, and was continued from May until October, 1902, with the assistance of the Mexican Government. The object was to investigate particularly yellow fever and other diseases common to Mexico and the United States. The report which has been submitted to the Government of the work accomplished is an admirable, brief presentation of what has already been learned regarding the relation of the mosquito to yellow fever and of the added knowledge which this special investigation has brought.

To persons unfamiliar with the extremely interesting history of the development of our knowledge regarding the etiological rôle of the mosquito, this pamphlet may be read with great profit. A brief description is given of the *Stegomyia fasciata*, its natural breeding places and its importation into this country. It may not be generally known that this species of mosquito is not native to the United States, but has become domesticated largely through the medium of commercial intercourse. As a result of this invasion, certain infected regions may be marked out with a considerable degree of accuracy, and this has been done with much benefit to future students of the disease. The chief aim of the working party to which we have alluded was the identification and classification of the specific organism of yellow fever, a matter which has hitherto remained undecided.

The writers of the report give an excellent synopsis of previous investigations, giving very justly much credit to Major Reed, whose work in connection with the scientific proof of the mosquito theory, earlier advanced by Finlay, is now universally known. In carrying out the further investigation, Dr. Parker and his colleagues studied with much care fresh blood microscopically and bacteriologically, made bacteriological examination of organs at autopsy and conducted various experiments relating to the transmission of the disease by mosquitoes. All of these facts and very many others of much interest are given in a space of forty-eight pages, to which are added forty-three very beautiful illustrations of the mosquito *Stegomyia fasciata*, both in its macroscopic and microscopic relations. These illustrations are by far the most elaborate in color and execution that we have seen on this subject, and should be given wide circulation in connection with the accompanying text. The general conclusions which the writers reach on the subject are included in the following four statements:

That the bacteriological examination of the blood of cases of yellow fever during life and the blood and organs at autopsy performed immediately after death in uncomplicated cases is negative.

That *Stegomyia fasciata*, when contaminated by feeding on a case of yellow fever forty-one and a half hours after the onset of the disease and subsequently fed on sugar and water for twenty-two days one and a half hours, can, when permitted to feed on a non-immune individual, produce a severe attack of the disease.

That *Stegomyia fasciata*, contaminated by feeding on a case of yellow fever and after varying periods killed, sectioned and appropriately stained, presents with regularity a protozoan parasite, the *Myxococcidium stegomyiæ*, that can be traced through a cycle of development from the gamete to the sporozoite.

That *Stegomyia fasciata* fed on blood from a case of malarial fever, on normal blood or artificially fed, does not harbor the parasite.

The importance of this work and the addition which it brings to our knowledge of the subject can hardly be questioned.

THE DIAGNOSIS OF INSANITY AT SIGHT.

A PAPER which departs very widely from the usual type presented at medical meetings was read by Dr. Steven Smith of New York at the meeting of the American Medico-Psychological Society recently held in Washington. The subject of this communication was "How Dr. Brigham Met the Challenge to Diagnose Insanity at Sight." This paper was regarded as having so large an element of popular interest that it has been republished, we presume in full, in a recent number of the *Outlook*. We question somewhat whether this contribution should lay claim to medical value, but we are nevertheless of the opinion that such a variation of the routine of medical meetings, when told in the delightfully graphic style of this paper, must be welcome in the sometimes gloomy waste of so-called scientific productions.

The story narrated by Dr. Smith simply is that during the period toward the end of the first half of this century, when the negro question was already under active discussion, a negro was suspected of the crime of murder. He later confessed to the crime, but showed such signs of mental alienation that the incensed public feared his escape from justice on this ground.

When his trial finally took place, after threats of lynching had been successfully met, William H. Seward, Esq., impressed with the belief that the negro was insane, and also eager to stand between him and the popular clamor for his death without trial, undertook the defence. The details of the trial are told with much vividness, but the climax was reached when Dr. Amariah Brigham, then superintendent of the Asylum for the Insane at Utica, was called as an expert for the defence. He believed in the man's insanity, and, after undergoing with much composure a cross-examination of great severity at the hands of the prosecuting attorney, he finally was asked the question whether or not he could diagnose insanity at sight. Dr. Brigham replied emphatically that he could. He was then called upon by the attorney-general to point out to the court and jury an insane person in the audience. Rising from his chair, Dr. Brigham scanned with keenest scrutiny row after row of those who were witnessing the trial. After five hundred faces had been studied, he finally fixed his attention upon a certain person, stretched out his arm, pointed his finger toward one of the rear rows of seats, and said, "There is an insane man." The event justified his diagnosis, and the lunatic — for such he was — was finally removed with difficulty from the court room. This practically ended the trial, but the issue of the case was the conviction of the criminal for murder in the first degree. It was a concession to public opinion. He died later in prison, completely demented.

The final statement of the account, as given in the *Outlook*, is "an autopsy confirmed the correctness of the defence — insanity." All of this is most entertaining as a story which should be kept alive, but as a contribution to medical literature we are compelled to feel that it overshoots the mark. Even now the diagnosis of insanity, as ordinarily understood, by a study of the brain, is often impossible, nor have we reached that stage of perfection in observation which permits us to detect the signs of insanity in many a person who has passed beyond the bounds of reason. This, however, occurred in 1846, and it may be that our more refined methods of diagnosis have detracted somewhat from the powers of observation which Dr. Brigham is claimed to have so fully developed. This, at least, is a charge which is occasionally brought against the modern physician, and possibly this entertaining story may give it weight.

DR. MORRILL WYMAN.

IN this issue of the JOURNAL we offer a contribution to the memory of the late Dr. Morrill Wyman of Cambridge. The physician, however great his professional reputation may have been, usually receives at his death but scant acknowledgment from the world at large unless his life work has led him quite beyond the bounds of medical science. Dr. Wyman was a man whose personality and good citizenship, as well as his conspicuous contributions to medical knowledge, make such a memorial as this which we publish to-day peculiarly fitting. The writers, all prominent in the professional life of this and the neighboring city of Cambridge, knew Dr. Wyman personally, and each in his own way adds something of appreciation to the brilliant record of the great Cambridge physician. No doubt such a tribute, coming from his colleagues, would have been far more welcome to Dr. Wyman than a more fulsome, but less appreciative, because less well-informed, estimate of his character and work.

MEDICAL NOTES.

THE ENGLISH CANCER RESEARCH FUND.— The first annual meeting of the committee of the Cancer Research Fund was held in London, July 13, under the chairmanship of the Hon. A. J. Balfour. The work has been prosecuted for so short a time that nothing definite in the way of progress was given out at the meeting. It was, however, stated that the scheme of investigation proposes wide study in the various lines which may lead to a solution of the ultimate problem. To carry out this proposed plan Mr. Balfour very wisely places much stress upon the fact that in a research of this character immediate results may not be expected, and that to carry out such an investigation to its end requires a very large financial backing. It was further stated that £43,000 are still needed for the completion of the endowment.

REGISTRATION OF CONSUMPTIVES. — An ordinance has become law in Kansas City, according to the *Journal of the American Medical Association*, without the approval of the mayor, which provides that all persons suffering from consumption in an infectious stage must be registered with the board of health and must follow the instructions as to isolation and treatment made in each case by the city physician. The lay press says that the law is aimed primarily at the negroes, a large percentage of whom have con-

sumption, and who in their conduct on the streets and in crowds show no care for the danger to public safety from the germs of the disease.

INTERNATIONAL GOLF. — The *British Medical Journal* informs us that the annual golf match between members of the British Medical Association was played on the links of the Swansea Club. The course is very sporting and although the weather was showery the round was most enjoyable. It was agreed to make the sides England *v.* the Rest of the World. The game ended in favor of England by 8 matches to 2.

BEQUESTS TO IRISH HOSPITALS. — One result of the visit of King Edward to Ireland appears to be a bequest of $250,000 from Lord Iveagh for the benefit of both Catholic and Protestant hospitals in Dublin. This amount of money is given in memory of the King's visit.

HOSPITAL BUILDING IN NEW YORK STATE. — The *New York Medical Journal* makes note of the following activity in the construction of hospitals in New York State: At Albany a hospital for contagious diseases is about to be built, the ground for which has already been broken. Improvements are also being made in St. Peter's Hospital of the same city. At Buffalo $125,000 has been appropriated for a new marine hospital, of which $100,000 are to be expended for the building. In New York City, Bellevue Hospital has acquired additional land, which will be used for the enlargement of its buildings. The cost of this work is estimated at about two million dollars. Under the auspices of Dr. Peterson, president of the State Commission in Lunacy, it is also announced that a site in Washington County will be purchased for the erection of a new insane hospital, the necessity for which is brought about by the overcrowding at the King's County Institution. The final cost will probably exceed one million dollars, although the commission at present has but $50,000 appropriated by the last legislature.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Aug. 19, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 24, scarlatina 9, typhoid fever 20, measles 9, smallpox 0.

BOSTON MORTALITY STATISTICS. — The number of deaths reported to the Board of Health for the week ending Aug. 15 was 207, as against 201 the corresponding week last year, showing an increase of six deaths and making the death-rate for the week 17.88. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 22 cases, 4 deaths; scarlatina, 19 cases, no deaths; typhoid fever, 19 cases, 5 deaths; measles, 12 cases, no deaths; tuberculosis, 16 cases, 15 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 10, whooping cough none, heart disease 13, bronchitis 2, marasmus 7. There were 13 deaths from violent causes. The number of children who died under one year was 66; under five years, 69; persons over sixty years, 35; deaths in public institutions, 62.

TYPHOID FEVER AT LOWELL. — It is reported that since Aug. 1 about twenty-five cases of typhoid fever have appeared in Lowell as contrasted with none during the same period last year. The outbreak is attributed to the fact that by accident river water gained access to the city mains during the excitement consequent upon a fire. Measures will probably be taken to prevent the recurrence of such an accident.

NEW YORK.

REGISTRATION OF BARBERS. — The registration of barbers, in accordance with the act passed at the last session of the Legislature, was completed in New York on August 15, and the President of the Board of Health has announced that the rules for barbers carrying out the provisions of the Sanitary Code required by the act will be rigidly enforced after Sept. 1. Among them are rules prohibiting the use of sponges and of powder puffs. Other rules are the following: Combs, razors, clippers and scissors must be thoroughly cleansed by dipping them in boiling water or other antiseptic after every separate use thereof. No alum or other astringent shall be used in stick form. If used at all to stop the flow of blood, such application must be made in the form of powder.

A NEW DISPENSARY. — The Sydenham Society, a new organization which is apparently composed of Jewish physicians, has opened a dispensary and small hospital in East 116th Street. The lower floor of the building is used for the out-patient department and on the upper floors are accommodations for twenty patients.

A CENTENARIAN. — Mrs. Alice Baudette, whose two brothers served as soldiers in the War of 1812, died at Glens Falls, N. Y., on August 13, at the reputed age of one hundred and three years.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUG. 8, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 2,696; under five years of age, 1,183; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,039, acute lung diseases 153, consumption 272, scarlet fever 21, whooping cough 21, cerebrospinal meningitis 18, smallpox 1, erysipelas 4, measles 11, typhoid fever 42, diarrheal diseases 611, diphtheria and croup 38.

From whooping cough, New York 10, Chicago 5, Baltimore 3, Providence 1, North Adams 1, Hyde Park 1. From erysipelas, New York 1, Chicago 1, Woburn 2. From smallpox, Fall River 1. From scarlet fever, New York 13, Chicago 1, Baltimore 4, Providence 2, North Adams, 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending July 25, the death-rate was 13.4. Deaths reported, 3,874; acute diseases of the respiratory organs (London) 132, whooping cough 74, diphtheria 49, measles 111, smallpox 5, scarlet fever 40.

The death-rate ranged from 5.7 in Tottenham to 21.1 in Great Yarmouth; London 12.7, West Ham 10.4, Brighton 12.5, Portsmouth 10.4, Southampton 10.4, Plymouth 15.4, Bristol 9.7, Birmingham 14.1, Leicester 13.0, Nottingham 11.2, Bolton 19.2, Manchester 16.0, Salford 15.7, Bradford 12.9, Leeds 16.6, Hull 13.0, Newcastle-on-Tyne 12.4, Cardiff 12.7, Rhondda 14.4, Liverpool 18.0, Bury 20.6, Wigan 14.3.

METEOROLOGICAL RECORD.

For the week ending Aug. 8, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE FOURTEEN DAYS ENDING AUG. 6, 1903.

PETTUS, W. J., assistant surgeon-general. Granted leave of absence for twenty days from Aug. 10. Aug. 5, 1903.

AUSTIN, H. W., surgeon. Granted leave of absence for one month from Aug. 6. July 30, 1903.

CARTER, H. R., surgeon. Granted leave of absence for one month from Aug. 4. Aug. 1, 1903.

STONER, J. B., surgeon. Granted extension of leave of absence for one month from Aug. 1. July 28, 1903.

NYDEGGER, J. A., passed assistant surgeon. Relieved from duty at Sault Ste. Marie, Mich., and directed to proceed to the Immigration Depot, New York, N. Y., and report to Surgeon G. W. Stoner for assignment to duty. Aug. 3, 1903.

ANDERSON, J. F., passed assistant surgeon. To proceed to Marietta, Conewaga and Swiftwater, Pa., and Baltimore, Md., for special temporary duty. Aug. 5, 1903.

DECKER, C. E., assistant surgeon. Granted extension of leave of absence, on account of sickness, for fifteen days from July 15. July 20, 1903.

APPOINTMENTS.

Norma Roberts of Pennsylvania, George L. Collins of Massachusetts, Harvey G. Ebert of Washington, William M. Wightman of California, Herbert M. Manning of the District of Columbia and Frederick C. Smith of Minnesota, commissioned as assistant surgeons (recess) in the Public Health and Marine Hospital Service. July 25, 1903.

PROMOTION.

G. W. Iltis, pharmacist of the third class, promoted to be pharmacist of the second class, effective April 24, 1903.

REINSTATEMENT.

William C. Phillips reinstated as pharmacist of the third class. July 15, 1903.

Pharmacist H. E. Davis suspended from duty and pay for a period of thirty days from July 27, 1903.

RECENT DEATHS.

MICHAEL F. MCGRATH, M.D., died at Fishkill-on-the-Hudson on Aug. 11, of pulmonary tuberculosis. He was thirty-five years of age and a graduate of St. Francis Xavier College and the College of Physicians and Surgeons, New York.

BOOKS AND PAMPHLETS RECEIVED.

Handatlas der Anatomie des Menschen mit Unterstützung. Von Wilhelm His, Professor der Anatomie an der Universität Leipzig bearbeitet von Werner Spalteholz ao. Professor an der Universität Leipzig und Custos der anatomischen Sammlungen. Dritter Band, 2. Abtheilung. Leipzig: Verlag von S. Hirzel. 1903.

Verhandlungen des Vierten Nordischen Kongresses für Innere Medizin. 1902.

Ureteritis in the Female. By Edgar Garceau, M.D., of Boston. Reprint. 1903.

Original Articles.

THE INVALID'S EGYPT.

BY F. GORDON MORRILL, M.D., BOSTON.

EGYPT of the invalid and Egypt of the tourist differ essentially in many respects; and while I have defined the intention of this paper by its title, there are portions of it which apply to the robust "globe trotter" — for there are certain precautions which should be observed by all who visit the country, whether for health or pleasure.

One's preconceived notions of the Egyptian climate are seldom correct; for notwithstanding all that has been said and written about it, the average person still fancies that it never rains in the Land of the Pharaohs, that the air is everywhere balmy, and pictures himself as dressed in white ducks and being borne up the Nile by gentle zephyrs (or steam power) from Cairo to Wadi Halfa.

Now as a matter of fact there are two Egypts, an Upper and a Lower, and these two sections differ as much in temperature and relative humidity as do Boston and Washington, or Paris and Nice.

It can rain as hard in Cairo as in New York (though far more seldom), and as for the Nile, it is often very cold during the season when foreigners are likely to be on it, and those who remain on deck after sunset often have cause to repent.

Lower Egypt has but one station which has genuine claims to consideration as a resort for invalids during the *entire season*, and that is Helouan. If for any reason it is necessary to pass the winter near Cairo, there is no other place where the temperature is so even and the air so dry.

It is literally surrounded by desert, and there is no vegetation near enough to produce any perceptible effect upon the atmosphere.

It rains there (usually a shower) about as frequently as in Cairo,— say once a fortnight during the season,— but it is entirely free from the mist which usually hangs over the capital until 10 A.M.

The mean average maximum temperature is 71.5° F. and the like minimum 50° F., with absolute extremes of 97° F. and 37° F.

These figures and all which follow in this paper apply to what is usually recognized as "the season" — Dec. 1 to April 1.

The drop in the temperature immediately after sunset is slighter and less abrupt than in Upper Egypt; but the thermometer during the daytime is 10° and during the night 5° lower than at Assouan.

The relative humidity is 55.5°, which is 14.5° greater than at Assouan, but rather less than that of Mena House or Ghezireh. There is a golf links, two good hotels and two or more comfortable *pensions*.

The facilities for walking and riding are excellent. The large and modern bathing establishment is well installed, but lacks an efficient heating apparatus.

An occasional *khamsin* (sand storm) constitutes an unpleasant feature in the spring, and flies and mosquitoes are persistent and more or less abundant.

Cairo is within easy reach by good trains, and while Helouan can hardly be compared with Assouan as a health resort, it is certainly the best in Lower Egypt, and a good place of residence for any one not quite strong who wishes to see something of Cairo between Nov. 20 and Christmas, by which time he ought to go further south.

Again, in the spring there prevails a certain amount of malaria of a mild type from which no place in Lower Egypt is entirely exempt, and to which an invalid should so far as possible avoid any chance of exposure.

Cairo the Fascinating, while not suitable as a residence for such as visit the country for reasons of health, is safe enough for invalids during the daytime, provided certain precautions are observed. The City of the Caliphs has no comprehensive system of drainage, and *in the native quarters* Oriental customs permit filth of every description to soak into the ground.

Mosques, bazaars, workshops and houses are as bad as possible from a sanitary point of view; and yet the abundant sunshine renders life possible under conditions which would rapidly kill off the population in a damp climate. In the European quarter one finds modern plumbing and carefully supervised cemented cesspools. A prudent resident of this section stands as good a chance of keeping well during the winter months as in other large cities.

The climate of Cairo is better than that of any place on the continent of Europe during the winter months, but is not ideal.

None of the hotels are provided with a really efficient heating plant, and open fireplaces in bedrooms are rare exceptions. There are many fairly cold (and a few rainy) days between Dec. 20 and March 1 (I am speaking of an average season), and the complaints of those who "thought that Cairo was always warm" are frequently heard.

There are certain special dangers to guard against — the bazaars should not be visited after a rain until the surface of the ground at least is thoroughly dry; no refreshments should be taken in any shop, and the night air must be avoided so far as possible.

Perhaps the safest and most comfortable place for one who does not care for Helouan, or to whom a desert climate is not a prime necessity, is Ghezireh Palace Hotel, which is well heated, surrounded by an extensive and beautiful garden, opposite a club for outdoor sports and within twenty minutes' drive of the center of the city.

Mena House, near the pyramids, may be considered a desert station after the annual inundation of the Nile (which floods the golf links and surrounding territory) has subsided; but the climate is not so good as that of Helouan, as the prevailing wind blows directly from the delta, which is composed of rich cultivated lands, numerous canals and other water surfaces.

The only other place worthy of consideration in

Lower Egypt is Ramleh, which is situated on the sea coast a short distance from Alexandria, where a person in delicate health may find comfortable quarters after April 1 and remain a fortnight or more before leaving the country, or in case of early arrival may stay until the good hotels of the other resorts are opened. The climate here is good at such times and *khamsin* winds infrequent.

Alexandria, Port Said and Ismailia are mentioned only as ports of entry and departure, and one's stay in any of them should be as brief as possible.

In Upper Egypt there are two stations only where comfortable hotels may be found — Luxor and Assouan.

The former may be reached by an excellent *train de luxe* in thirteen hours, or by "express boat" in four and a half days.

The air here is both warmer and dryer than that of any part of Lower Egypt, and the wonderfully preserved temples and tombs afford a boundless field for the enjoyment of such as are at all interested in Egyptology.

Before Assouan became well known, Luxor was the only health resort in Upper Egypt, and many invalids have recovered health or passed comfortable winters there.

It has not a *desert climate*, for its immediate surroundings consist of rich farming lands. The rainfall is slight (some seasons almost *nil*), and the relative humidity is 52.2° during the winter months and during the daytime 36.3° only. It is warmer here both by day and night than in any place in Lower Egypt; but the mean temperature range is large — 28.4°, with an abrupt decline at sunset.

Sand-storms are rare and flies and mosquitoes are fewer than they are in Lower Egypt, but more plentiful than at Assouan.

The facilities for walking and riding are good, and malaria is unknown. Luxor is a good halfway station for those who are en route either to or from Assonan, and a capital place for invalids who require the sort of mental exercise which Egyptology, even in a mild form, so readily induces.

Just below the First Cataract, and seven hours from Luxor by a narrrow-gauge road, over which roll phenomenally dirty cars, is Assouan, which is far away the warmest, dryest and cleanest place in all Egypt. Aside from actually camping in the desert there is no way of breathing so pure an air as by staying here, and the climate is nearly perfect, taking the season through.

The average mean maximum temperature is a fraction over 80° F. and the like minimum (6 A.M.) 54° F. The relative humidity between 10 A.M. and 6 P.M. averages 30.5° F., while that of the twenty-four hours is not quite 41°. There is an almost complete absence of cultivated land in the neighborhood of the best situated hotel (the Cataract), which is due to the fact that the banks at this point are so steep as to absolutely preclude any inundation of the Nile. A refreshing wind blows from the north and northwest and gives life to the air, and seldom blows too hard for comfort.

One notices here an agreeable absence of the howl for *backshish*, flies and mosquitoes. Walking, riding and boating facilities are excellent; good police and sanitary regulations are well enforced, and everything is done by the authorities for the comfort and safety of visitors.

In April, 1900, there was a shower which lasted nearly ten minutes; but since then there has been no rain so far as I have been able to ascertain.

During the past season (1902–3) there were three days when the sun was hidden and the wind so strong as to preclude riding in the desert; but with these exceptions there prevailed the perfection of fine weather, with a clear blue sky which stretched from horizon to horizon. Between Christmas and Feb. 1 one may expect some fairly cool days (in the shade) and a few really cold nights. Open fires, if not too large, are grateful in the evening at this time of the year.

The night air is harmless if one is well wrapped, and steel shavings fresh from the lathe show absolutely no signs of rust after weeks of free exposure.

The apprehension that closing the gates of the great dam above the cataract, and consequent holding back of an immense body of water during the winter months, might prove detrimental to the climate has proved groundless, and Assouan as a health resort remains without a rival in Egypt.

Malaria is unknown, and there has been no case of enteric among visitors during the past three seasons.

One is frequently asked as to what sort of clothing should be taken to Egypt, and the answer depends upon what part of the country is to be visited and during what months. For Lower Egypt between Christmas and March 10 one should dress as he would in New York or Boston in the late autumn or the month of April. In Upper Egypt the same rule obtains in January and the first two weeks of February, while before and after this period summer garments are worn.

Among the precautions to be observed (most of which apply to the well and weak alike) is not to move about the country too rapidly and try to see too much. Dr. F. M. Sandwith (of London and Cairo) tells me that he is constantly meeting with cases of nervous exhaustion, particularly among Americans, who have come to grief in this way.

It is just as well to avoid drinking Nile water everywhere excepting Assouan, where it can be safely used (filtered), coming down as it does through that sparsely populated waste of rock and sand known as the "Military Soudan," where it is free from the constant pollution to which it is subjected further down stream.

Milk from the ordinary sources of supply is not always safe unless boiled, and should pure milk be required for drinking purposes it must be obtained from a good dairy, of which there are several near Cairo and (on a far more modest scale) one at least at most of the other stations.

Moreover, this special milk is the product of

the cow, not the buffalo, which latter, while rich in cream and very nourishing, does not suit all palates.

Eating or drinking *anything* outside reputable hotels and restaurants is attended by a certain amount of risk, as any one familiar with native habits and customs can testify.

Egypt is a particularly easy place to "take cold" in, or as the English say, "for taking a chill." The contrast in temperature between sunshine and shade is great, and the delightful experience of lunching in the shadow of a picturesque ruin after a long excursion is likely to be followed by unpleasant results. Drafts, *even of warm air*, are to be avoided, and the least perceptible drop of temperature is a signal to the prudent for putting on overcoats or wraps.

In the matter of diet nearly all visitors fall into the error of eating too much and in too great variety. This often proves to be a grave mistake; and while they can scarcely be expected to adopt the *regime* of the natives,— whose diet consists principally of cakes made of an inferior flour of sorghum or maize, beans, dates, sesame (or linseed) oil, buffalo (or goat's) milk, and occasionally a little fish or the flesh of the goat,—avoidance of the richer sorts of food and restriction in the use of red meat and alcohol certainly tend to keep one well.

As I have previously said, the Nile is a cold river at times, and particularly so at night. Moreover on the lower part, say between Cairo and Assiut, mists are by no means uncommon, and every precaution against colds must be observed. Invalids ought never to sit on deck after sunset, and well people who do so should be warmly clad. Between Luxor and Assouan the river is far less chilly and one can easily arrange to make close connection with a steamer after reaching Luxor by train. So far as making the regular tourist's excursion up the Nile is concerned, the exposure and fatigue involved are enough to test the endurance of the most robust.

Any prolonged exposure to the sun's rays, particularly while riding or walking, is exhausting to one not acclimated; and the statement that a two hours' excursion in Egypt is fully equal to a half day's similar exertion in a temperate climate is quite true.

Many are inclined to laugh at those who wear solar topees and carry sun umbrellas; but I have seen one scoffer (who insisted upon making long excursions with no protection for his head save a black derby hat) fall insensible at the dinner table and require repeated hypodermic injections of brandy and strychnia before he could be revived.

For invalids and semi-invalids the Mecca is undoubtedly Assouan, unless some very potent reason exists for remaining within touch of Cairo, in which case they have the choice of Ghezireh Palace or Mena House after Jan. 1, or Helouan for the entire season in case a *desert* climate is indicated.

I have had a considerable personal experience of most of the stations, and am quite convinced that Assouan — where I have seen numerous cases of cardiac, renal and pulmonary troubles, rheumatism and nervous exhaustion, show radical improvement after a few weeks' sojourn — is by far the safest and best. It can be reached from Cairo in twenty-two hours by train, one week by "express" boat, or two days and a half by combination of both. The natives here enjoy better health than those in Lower Egypt, and during the late cholera epidemic not a case occurred in the town.

Further up the Nile is Wadi Halfa, but the climate there is neither so warm nor dry as Assouan, and as for Khartoum and Omdurman, one finds cold weather and blustering winds in winter, and, so far as I can ascertain, the chief pleasure of the journey is the opportunity to get rid of one's accumulations of dust and sand in the baths of Abu Hamed.

An invalid who wishes to obtain the best results from the climate of Egypt should arrive in Cairo not later than Dec. 1 (Nov. 20 would be better) and go directly to Assouan, to remain until the middle of March or even later, when he may safely go to Cairo by river if he so elects, and after a short stay at any one of the three stations (Ghezireh, Helouan or Mena House), make his way to Ramleh, where the hotels open April 1, to remain until the time arrives for leaving the country.

The common mistake made is that of choosing too early a sailing date. About the middle of April is the best time; for if one reaches the continent (or Sicily or Corfu) before the 20th, the weather will very likely be found too cold for comfort. Palermo and Taormina are both charming half-way stations, and Corfu (while a little damper) may be regarded in the same light. Of the three places Taormina is the best, for its elevation is sufficiently great to raise it above the mist which prevails in the spring along the entire coasts of Sicily and southern Italy.

THE TREATMENT OF DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM BY MASSIVE DOSES OF STRYCHNIA, WITH SPECIAL REFERENCE TO TABES DORSALIS, PROGRESSIVE MUSCULAR ATROPHY, OPTIC NERVE ATROPHY AND PSEUDO-MUSCULAR HYPERTROPHY.[1]

BY GRAEME M. HAMMOND, LL.B., M.D., NEW YORK, N. Y.

I HAVE selected for my subject to-night the medicinal treatment of some of the degenerative diseases of the nervous system. I am aware it is an unusual subject and that the neurologists generally concentrate their energies in investigating and interpreting the remarkable changes that take place in the nervous system from disease, the relation of these changes to the symptoms evinced and the localization of the disease in the nervous system. The study of these subjects is of vital importance. They are not only of absorbing interest in themselves, but they lead up to the final goal, — the application

[1] Read before the Boston Society of Psychiatry and Neurology, April 16, 1903.

of the sum total of our knowledge to the intelligent treatment of disease. Each new discovery in regard to the structure, the development, the nutrition of the cell body, and every addition to our knowledge relating to the manner in which disease processes degenerate and destroy the cell bodies, must necessarily instruct us in regard to the best methods of preventing and arresting degenerations, which when they once begin so vitally affect the welfare of the individual.

Those of you who can look back a few years to the time when the lesion of tabes was considered to be an inflammation of the spinal cord can readily comprehend why all remedies brought to bear against it failed, and why because of our helplessness it was considered to be an absolutely incurable disease. Later, when the close relationship of syphilis to tabes was demonstrated, and it was seen that the most energetic antisyphilitic treatment failed to arrest the advances of the morbid process, the belief in the incurability of tabes became, if possible, more fully established. But with the acceptance of the neuron doctrine, the knowledge of the structure of the cell bodies,—incomplete as it probably is,—the manner in which the cells degenerate and the relation of toxins to this degeneration, the conception of tabes has materially changed. With a clearer understanding of the nature of this disease, and a more intimate knowledge of the process of degeneration, it does not seem either illogical or presumptuous to believe that some remedial agent will be found capable of overcoming toxic influences and arresting the consequent degeneration, or of arresting degenerations due to other causes at present imperfectly understood, such as that which occurs in the muscle elements in pseudo-muscular hypertrophy or in the optic nerve in simple retinitis pigmentosa.

I was led to consider the use of massive doses of strychnia in degenerative diseases by the beneficial effect produced in the treatment of certain cases of tic douloureux by comparatively large doses of that drug. In more than one case of this disease it has been clearly demonstrated that the symptoms depend upon a more or less profound degeneration of the cell bodies with their axons in the trigeminal nucleus, the ganglia and the nerve. In some cases the primary lesion seemed to be in the vascular system supplying the trigeminal mechanism, and the degeneration of the nervous elements seemed to be the direct result of the consequent deprivation of nutrition.

It seems probable, in the light of our present knowledge, that all degenerations result from one or more of the following causes: (1) Some toxin which, acting in a chemical manner, destroys the substance of the neuron, or by acting upon its metabolic mechanism prevents the assimilation of nutrition upon which its life depends; (2) some disease of the blood vessels causing their partial or complete obliteration or some other obstruction to the blood current which so deprives the neuron of its nourishment that its vitality must necessarily fail; and (3) some traumatism causing hemorrhages, lacerations or compressions.

The treatment of degenerations due to the latter cause has no place in this paper, as it does not seem probable that medicinal treatment can either eradicate the cause or arrest the disease under the circumstance. It occurred to me that possibly strychnia in doses far in excess of those generally administered, and continued for a long time, might favorably influence, in some instances at least, the degenerative process of tabes (from the other causes), and so improve the nutrition of the neurons that degeneration might either be arrested or at least delayed. There was little or no precedent for my guidance, except for the hint given me in the cases of tic douloureux already alluded to. I began a series of experiments, selecting a few cases from several diseases. My results I purpose to present to you this evening. The cases presented do not comprise all of the series. I have purposely refrained from including in my report all cases that have not been under observation for at least a year, with the exception of one case of retinitis pigmentosa and one case of progressive muscular atrophy. The former case has been under observation nine months and the latter case I report because the treatment had apparently no effect at all in arresting the progress of the disease. I have excluded all cases who have not been a year under treatment, because my experience has led me to believe that the prolonged administration of the remedy is essential before any definite conclusion can be reached in regard to the efficacy of the treatment and because I wished to exclude the possible hypothesis that any improvement obtained was only apparent and due to the influence of suggestion, which in some instances seems for a time to benefit patients who, when suffering from an incurable malady, undergo some new and unusual form of treatment.

The present paper is based on the results obtained in the treatment of eleven cases. There are four cases of tabes, three cases of optic nerve atrophy, three cases of progressive muscular atrophy and one case of pseudo-muscular hypertrophy.

TABES DORSALIS.

The first case of tabes in which large doses of strychnin were administered came to my clinic at the Post-Graduate Hospital in March, 1900. He was in an advanced stage of the disease, and could only walk with the assistance of a person on each side of him. The disease had progressed rapidly during the past year. The general symptoms of tabes were well marked. He had contracted syphilis about fifteen years before, and the symptoms of tabes had been in evidence for about six years. It was decided to give the strychnia hypodermatically in increasing doses. In order that this plan might be successfully carried out, Dr. Altman, one of my assistants, visited him daily, and personally gave him one injection each day. The dose at first was the 1-50 of a grain. This was gradually increased

until daily doses of 4-5 of a grain were reached. There never were at any time during which the treatment was continued any symptoms of strychnin toxemia.

The result of the treatment was not encouraging at first. The disease advanced apparently unchecked until he was totally unable to walk at all. At this time the dose had been increased to about 1-3 of a grain daily. From this time his locomotion improved until he was able to walk with very little assistance. None of the symptoms entirely disappeared, but it is equally true that he was benefited in many ways. The improvement consisted in a complete arrest in the advancement of the disease, a marked diminution in the severity and frequency of the attacks of pain and in a noticeable improvement in the power of locomotion. He became able to walk about the house alone by taking hold of different pieces of furniture, and could walk in the street with the assistance of a cane and one person to assist him. He has had no treatment for about year, but so far has not suffered any relapse.

The second case was sent to me by Dr. Troxell of Pittston, Pa., in March 14, 1900, — about two years ago. He was about forty years of age, and had contracted syphilis about eight years before. For the preceding two years he had suffered in a slight degree from the characteristic pains of tabes and from peculiar indescribable sensations in the legs, which would come on suddenly and always caused him to fall. A physical examination showed the Argyll-Robertson pupil. The knee jerks were absent. Romberg's symptom was present in a slight degree. He walked well and without any noticeable ataxia in gait, though he admitted he had to exert unusual care in walking over slippery surfaces. There was slight incontinence in urine. His general health was not good and his nutrition was much below par.

Here was a case in the early stage of tabes in which it was possible to begin treatment before the sensory neurons were in a state of advanced degeneration.

The initial dose of strychnia was 1-40 of a grain three times a day. The dose was gradually increased to 2-3 of a grain three times a day.

During the first three months of treatment there was little or no change in his condition, except that his general nutrition and health were greatly improved.

After the third month the pains ceased; the peculiar sensations in the legs and the consequent falls no longer troubled him, and he regained control over the bladder.

As the disease ceased to advance the dose of strychnia was never increased beyond 2-3 of a grain. After the first year it was reduced to 1-4 of a grain, and now he takes 1-8 of a grain.

At the present time, over two years after treatment began, it may be safely said the disease has ceased to advance. He still has the characteristic pupils and the loss of the knee jerks, but the other symptoms have entirely disappeared. In this case there was certainly very little improvement before the end of the first three months.

The third case began treatment March 25, 1901. She had contracted syphilis ten years before. The symptoms of tabes had been observed for about two years. She suffered severely from pains in the legs. The Argyll-Robertson symptom was present, the knee jerks were absent, Romberg's symptom was well marked. The gait was ataxic, so much so that it was decidedly noticeable. There were also numbness in both hands, with some loss of finger dexterity, and paralysis of the left levator palpebræ and internal rectus muscles. Her general health was not good. She was anemic and had lost a great deal of flesh, her weight then being one hundred and eleven pounds.

She was at first given strychnia in 1-40 gr. doses three times a day. The dose was gradually increased until a maximum dosage of 2-3 of a grain three times daily was reached. During the first two or three months of her treatment no amelioration in her condition was noticeable, except that her general health improved and her weight increased. After this some of her symptoms gradually improved — the numbness in her hands entirely disappeared; the severe pains diminished, until finally they seldom troubled her; she could stand better with the eyes closed, and her powers of locomotion increased quite remarkably. At the present time — over two years after treatment began — the third nerve is still paralyzed; the pupils remain unchanged; she has no knee jerks, and Romberg's symptom can be elicited, though it is less marked than it was. But her pains have almost entirely disappeared. She has gained twenty-nine pounds in weight. The numbness in the hands no longer troubles her; she can use her hands as well as ever in her business (dressmaker); and her walking has improved so much that her disability is only apparent to a close observer. A week ago I saw her walk a plank sixteen feet long, one foot wide, and elevated eight inches above the floor level.

CASE IV. This case was sent to me by Dr. A. C., Combes on April 28, 1902. He had contracted syphilis twenty years previously. He had been treated with the usual anti-syphilitic remedies for a number of months without benefit — in fact, the disease was rapidly advancing. He suffered severely from pain. The Argyll-Robbertson symptom was present; the knee jerks were absent; Romberg's symptom was well marked, and the gait was decidedly ataxic. There was numbness in both hands and both feet, the left side of the face, the left half of the penis and left half of the anus. Physically he was very weak. He weighed one hundred and twenty-nine pounds. The initial dose of strychnia was the 1-50 of a grain three times a day. The dose was gradually increased until at the end of three months he was taking 1-6 of a grain at a dose. During this time there was no noticeable improvement. On the contrary, the symptoms generally were more pronounced than when he began treatment. But shortly after he began to improve. At the present time, — about one year after beginning

treatment, — he weighs one hundred and forty-four pounds, a gain of fifteen pounds. The pains have entirely ceased, the numbness is seldom appreciated. He walks well and can even run and jump. There is no change in the pupillary symptoms, the knee jerks are still absent, and there is slight unsteadiness in standing with the eyes closed. He attends to business daily. The maximum dose reached was 2-3 of a grain three times daily. He now takes about 1-2 a grain at each dose.

In this case the degeneration was progressing rapidly and continued to do so for three months after treatment began. At the end of that time he was almost unable to walk at all, and could only do so with the aid of a cane for support. The improvement in locomotion is quite remarkable. He is, of course, not well, but the degenerative process seems to have been arrested.

In none of these cases of tabes was there ever any attempt made to teach them to perform purposive co-ordinated movements according to Fraenkel's method.

OPTIC NERVE ATROPHY (RETINITIS PIGMENTOSA).

The first case had been under the care of Dr. Greuning for the past seven years. Her sight from the very beginning of the disease had steadily failed and the visual field had contracted to about one-fifth of the normal range. When I first saw her she could not read type smaller than No. 13, the letters of which measure 1-8 of an inch in length. I first saw her on Nov. 30, 1901. For the past six months her sight had failed rapidly. She also suffered from frequent attacks of absolute blindness, which, however, lasted only a few minutes. Her treatment began with the administration of strychnia in doses of 1-50 gr. three times a day. The dose was gradually increased until the daily dose was 3-4 of a grain three times daily. Repeated tests made after the first month of treatment showed the disease was making no further advance. On the contrary, slight improvement in the visual power was observed after the first six months, and progressed up to the point where she could read test type No. 9, the letters of which are 1-16 of an inch in length. Her visual field has not expanded and there has been no further improvement in vision, but it may be positively said that the atrophic process ceased after treatment began, and has not shown any tendency to resume its course during the past seventeen months. She is still under treatment and is taking about 1-2 a grain three times a day.

The second case — a young woman twenty-four years of age — was sent by me to Dr. Roosa in March, 1902. She had been under his observation for several months, and he reported that both optic nerves were in an advanced state of degeneration. Her visual fields were greatly contracted. She could not read any of the type on the test card, though some of the letters were nearly an inch long. She could distinguish parts of the face of a person standing before her, but her field of vision was so contracted that she could not see the entire face. Large objects not too far off could be distinguished.

Her treatment was similar in every respect to that of the previous case, except that the maximum dose reached was 2-3 of a grain three times a day. A recent examination made by Dr. Roosa shows that the disease has not progressed since treatment began. She cannot see any better than she could, but her sight is no worse than it was.

The third case is that of a lady about forty-two years of age, who consulted me July 18, 1902. She had suffered from retinitis pigmentosa for several years. Her sight was very defective and the visual field was greatly contracted. Her father died of dementia, and a brother, nearly her own age, has become entirely blind as a result of optic nerve atrophy. The initial dose of strychnia administered was 1-50 of a grain three times a day. The maximum dose reached so far has been 1-2 of a grain three times a day. The degenerative process has ceased to progress. Her vision has not improved, but her sight is as good to-day as it was when treatment began.

PROGRESSIVE MUSCULAR ATROPHY.

The first case — a young man eighteen years old — came to my clinic Jan. 25, 1901. About a year previously he began to develop the Aran-Duchenne type of progressive muscular atrophy. When I first saw him the atrophic process had invaded the muscles of the hands, forearms, arms and scapular muscles. He could not raise either arm above his head. Fibrillation was plainly in evidence. Strychnia, beginning with a moderate dose, was given and gradually increased until 1-2 gr. doses three times daily were reached. Now, over two years after treatment began, it may positively be stated that the atrophic process has ceased. His muscular movements are stronger and wider in range. He can now elevate both arms above the head. The atrophy is still noticeable in the affected parts. I can only claim in this case that a rapidly advancing atrophic process rather suddenly ceased to advance and that slight improvement has taken place.

The second case — a man forty-two years old — presented himself at my clinic in October, 1901, suffering from progressive muscular atrophy. He was a miner and had been exposed to many hardships. He had also acquired syphilis about twelve years previously. His disease was of the Aran-Duchenne type, and had existed about two years. Atrophy was well marked in the hands, arms and shoulders.

He was treated with gradually increasing doses of strychnia, the maximum dose reaching a little over 2-3 of a grain three times a day. His treatment extended during a period of a little over a year under my supervision. After remaining a few months at my clinic and finding the disease showed no tendency to advance, he returned to his home in Butte, Mont., and continued his treatment under the care of his physician, who wrote to me from time to time.

I ceased to hear from him in a little over a year. At the expiration of that time there had been no advance in his disease. On the contrary, his strength had increased to a slight but appreciable degree.

The third case — a woman seventy years of age — came under my care Oct. 3, 1901. She had always enjoyed good general health until about one year previously she contracted a severe case of grippe. Three months after her recovery she first observed difficulty in articulation. This was followed by difficulty in swallowing. Subsequently weakness, accompanied by atrophy, appeared in both hands and forearms. Fibrillation was a prominent symptom. On account of the steady development of the symptoms, the strychnia was increased rather more rapidly than was customary, and soon half-grain doses were reached, three times daily. The disease, however, became more and more pronounced, and the patient died in about nine months.

I feel quite certain that the treatment did not even delay the progress of the degenerative process to any appreciable extent. Whether her age militated against her recovery or not is a matter of conjecture, but I am inclined to believe that it did.

PSEUDO-MUSCULAR HYPERTROPHY.

The patient, nine years old, consulted me in January, 1902. There was no history of any other similar case in the family. The patient walked as early as most children, but never walked strongly. When he was three years old his mother noticed he had frequent falls, and when he arose from the ground it was accomplished with difficulty and in the peculiar manner characteristic of the disease in question. The disease has advanced steadily, and now involves the legs, arms and back. Pseudo-hypertrophy was present only to a slight degree. During the past year he had lost flesh rapidly. His weight was forty-nine pounds in winter clothing. He could not go up stairs without assistance, and was unable to get upfrom the floor at all. The initial dose of strychnia was 1-100 of a grain three times a day. The dose was gradually increased until at the present time he takes 2-3 of a grain at a dose.

His general health is good. He has gained six pounds in weight. The measurements of his arms and legs all show a slight increase in muscular development. He walks better, and can even run, but often falls while doing so. He can ride a bicycle, and mounts and dismounts unaided. He can mount the stairs one foot after the other, by holding the rail with one hand.

A decided improvement in muscular development is perceptible, but the main point of interest is that the rapid degeneration of the muscular system has ceased. The increase in volume of muscle and bodily weight is not due to pseudo-hypertrophy, because with the increase in size of the limbs he is able to perform better muscular movements than before he began treatment.

It has never before been my good fortune to see these results in any other case, though one case is, of course, inadequate to base any positive deduction on.

My purpose in regard to the treatment was, in the first place, to administer the strychnia in such gradually increasing quantities that large doses could be reached without submitting the patient to the dangers of strychnia toxemia, and, in the second place, to continue the use of massive doses for months at a time. My practice has been to begin treatment with a very moderate dose, usually the 1-40 or 1-50 of a grain three times a day, and to increase the daily dose by about the 1-500 of a grain. Sometimes in the beginning I have increased the dose by the daily addition of 1-200 of a grain, but always diminish this dose to the 1-500 of a grain after doses of 1-8 grain were reached. In the first case and in a few others, I have given the medication hypodermically once a day. I cannot perceive that the method possesses any advantages over giving it by the mouth three times a day, and it is certainly not so convenient. In my first case a daily dose of 4-5 of a grain was reached, and yet the patient showed no evidence of toxemia. That is the largest dose I have ever given. The maximum dosage varied in other cases according to the severity of the disease — from 1-4 of a grain to 2-3 of a grain three times a day.

In analyzing these cases the criticism may with justice be advanced that there are too few of them to warrant any definite conclusions. That this would be so of diseases in general cannot be gainsaid, but with the class of diseases under consideration any improvement or arrest in the degenerative process is so rare that when it occurs even in a single instance it becomes a matter of importance. This is particularly true for such diseases as tabes, optic nerve atrophy and pseudo-muscular hypertrophy. Certain cases of tabes have perhaps been benefited by other means, but I know of no cases of retinitis pigmentosa and pseudo-muscular hypertrophy which have ever been arrested by any means whatever. In regard to the case of progressive muscular atrophy so much cannot be said. There are rare cases which advance to a certain point and then the degeneration seems to stop spontaneously. The case reported may be one of these, yet the patient has regained some muscular power, the parallel of which I cannot ascertain has ever occurred in those cases of spontaneous limitation.

It would seem, therefore, taking all these cases together, that the massive doses of strychnia employed for a long time had undoubtedly been instrumental in arresting degeneration. In conclusion I would point out that in not a single instance was any patient restored to a normal condition. Such a result was not anticipated. Neurons once destroyed cannot be recreated, and hence perfect recovery can never be achieved.

I have never seen any improvemet in the pupillary symptoms, the knee-jerks have never been restored, and Romberg's symptom, though

diminished, never disappeared completely. But it will be recalled that in several of the cases a certain amount of improvement followed the treatment. It may be argued from this that a certain degree of the symptoms depends upon partial degeneration of the cell bodies, and that if this degeneration has not passed beyond a certain point, the partial or complete restoration of the cell amounts to more than a possibility.

It certainly seems possible, in some instances at least, to arrest degenerative processes in diseases which have hitherto been regarded as hopeless. If this is so, the importance of early treatment cannot be too strongly insisted upon. I confess I do not yet know whether the cessation of the degeneration will be permanent or not. It may be that the treatment has only checked the morbid process and that in two or three years' time, or even less, the degeneration may resume its progress. Time only can elucidate this point. I do not yet know how long treatment should be continued in order to permanently arrest the degeneration, if such a result can be accomplished. Further investigation is necessary before this question can be determined.

A BRIEF SUMMARY OF THE SURGERY OF THE ESOPHAGUS.[1]

BY SAMUEL J. MIXTER, M.D., BOSTON.

THROUGHOUT a considerable part of its course, the esophagus is more difficult of access than any other part of the alimentary canal, and hence the surgical procedures resorted to in other situations for the relief and cure of malignant and other growths are not available here. In the neck, however, its upper part is easily reached, and through the stomach something may be done to its lower part.

The chief causes calling for surgical interference are:

(1) Congenital malformations, such as double esophagus or pouches.
(2) Impacted foreign bodies.
(3) Malignant disease.
(4) Syphilis.
(5) Cicatricial stricture.

In the above list is not included spasm of the esophagus, really a medical rather than a surgical condition, although it is almost always cured by mechanical means, the passage of a full-sized probang. It should be mentioned, however, that Mickulicz, in a paper read before the American Surgical Association at its recent meeting in Washington, describes an exaggerated form which he calls "Cardiospasm," causing a very considerable fusiform dilatation of the lower part of the esophagus, for which he has performed gastrotomy, and through the opening forcibly dilated the cardiac orifice. He also suggests that this might be done by means of a suitable dilator, introduced from above.

[1]Read before The Massachusetts Medical Society, June 9, 1903.

(1) Congenital malformations are perhaps the most interesting and puzzling conditions met with. They may exist for years, and only suddenly be called to the attention of the patient by an inability to swallow, caused by some irritation produced by a rough ingested body, or they may be the cause of difficulty for years, and simply give the patient great discomfort and annoyance without endangering his life.

The case of a boy of ten years of age in my service at the Massachusetts General Hospital well illustrates an exaggerated form of this condition. He was brought in in the last stages of starvation, having had difficulty in swallowing for some years, the trouble being thought due to a small metal disk that he had swallowed when about four years old. He died soon after a gastrostomy had been performed under cocaine anesthesia, and on autopsy it was found that there were two tubes, one reaching from the pharynx nearly to the stomach, the other from the stomach nearly to the pharynx, with only a very small opening between them about three inches from the stomach.

Such a case might, I am sure, have been relieved, if not cured, in the manner to be spoken of later in connection with cicatricial contraction.

Congenital pouches are much more common, I have found, than is generally supposed. I have seen a considerable number of them, having seen three of them in my office in a month. They are usually small at first, and it is often late in life when they cause serious inconvenience. In these cases there is usually a history of a "small throat" since childhood, and finally regurgitation of food. These pouches are found in all parts of the esophagus, but fortunately are most often situated in the neck or behind the clavicles.

When the pouch becomes dilated it is almost impossible for the patient to swallow enough food of any kind to keep himself alive, though there is really no true stricture of the canal, the whole trouble being caused by the "spur" that acts as a valve.

When the pouch can be reached it may be excised and the esophagus sutured, the result being a perfect restoration of function. This is the ideal method of treatment, and should always be advised if the patient's age is suitable.

Much to my surprise, I have found that in many cases, when, for one reason or another, it was not thought best to resort to what must always be a difficult and fairly dangerous operation, I could by the passage of suitable bougies relieve the difficulty to a considerable degree, and the pouch would contract to a remarkable extent, so that the most distressing symptoms would disappear. The patient is given a large bougie which he learns to pass himself, and, though not cured, is made comfortable. This method of palliative treatment is worthy of trial in certain cases.

The passage of a bougie past such a pouch is not the easiest thing in the world, even to the

practised hand, as the opening of the esophagus is always on one side, and though large enough to admit an instrument of the largest size, may not be found by the tip of the bougie until after repeated trials.

And just here let me speak of esophageal bougies and their passage. Unfortunately in this country I have been unable to find a good quality or suitable sizes. The most perfect ones that I have seen come from Paris, are woven like urethral bougies, with olive tip, beautifully polished, and some of them are loaded with fine shot. The largest sizes should be at least three-fourths of an inch in diameter.

As has been said before, the lower opening is almost always on one side of the canal, and this is true not only of the congenital pouch but also of the acquired pouch that usually forms above malignant and cicatricial strictures. Hence, in order to find this opening it is well to have a bougie bent at a slight angle or even of a bayonet shape, so that the point will hug the side of the canal. This may be best done by a whalebone stylet, bent at the proper angle by heat, and forced down into the hollow bougie. It should always be remembered that even with these flexible instruments fatal injury may be inflicted, not only by passing them through a malignant growth into the mediastinum or elsewhere, or through the bottom of a congenital or acquired pouch, but also through the normal wall of the pharynx or esophagus. I have had one such accident. perforating the wall just at the beginning of the esophagus, when every attempt to swallow forced air and the contents of the pharynx into the cellular tissue, causing emphysema, inflammation and death.

The bulb probang is a useful instrument for exploration and diagnosis, but is not to be recommended for dilatation.

(2) Of impacted foreign bodies so much has been written that one need only speak of the great advantages of esophagotomy or gastrotomy in their removal, over prolonged or violent attempts with forceps, coin catchers and similar instruments.

In the hands of the expert laryngologist, the removal of foreign bodies from the esophagus by means of suitably constructed esophageal tubes or specula and forceps is often most successful, and should always be tried if the right man and instruments are at hand.

(3) Malignant disease of the esophagus is the most frequent cause for seeking surgical aid, and the one most hopeless of cure, though much may be done to avert starvation and to relieve the patient. It may occur in any part of the canal, and is seldom of such character that excision is of benefit. Sometimes, however, when the growth is very high up, it may be possible to remove it and bring the lower end of the esophagus into the lower angle of the wound. As a rule we must be satisfied with relieving the dysphagia.

Dilating the stricture is the most common method of treatment and is the most satisfactory in many cases, especially if food is introduced into the stomach at the same time. In many cases there is hemorrhage or irritation caused by every introduction of the bougie, and it is in these cases that Symond's method of permanent tubage is of great help. The tube is introduced over a small bougie as a guide and is left in for a week or two, the patient swallowing liquids easily until the tube becomes foul and stopped. Remember that a pouch almost always forms above a malignant stricture and hence the passage of a straight instrument may not be possible. For impassable or very irritable strictures of this sort, esophagostomy or gastrostomy is demanded. I have had most satisfactory results with esophagostomy in disease high up, and much prefer it to gastrostomy when it is possible.

(4) Of syphilitic strictures there is little to be said except that they are far from common, and should be treated with appropriate medication and dilatation.

(5) Cicatricial strictures of the esophagus, generally the result of swallowing strong acids or more generally alkalies, are among the most common and obstinate lesions of this canal that the surgeon is called upon to treat. Generally multiple and difficult to dilate, often with several acquired pouches, the resources of the surgeon are taxed to the utmost. Constant dilatation will serve to keep the canal patent, but often the canal is tortuous and even impassable to the smallest bougie. Sometimes an instrument may be passed *upward* from the stomach through a gastrotomy opening, but it is by no means easy.

It is in these cases that he method of Abbe — sawing through the stricture with astring — is of the greatest benefit.

Two years ago, before this society, Dunham of New York read a paper on this subject and demonstrated his beautiful method of getting a guide through a seemingly impassable stricture. His recent paper in the *Annals of Surgery* gives the whole story, so it need not be repeated here; enough to say that any one who has ever tried this method, as I have in a number of cases, cannot fail to be impressed with its ingenuity, simplicity and splendid efficiency. It is the greatest improvement in the technique of esophageal surgery in recent years. By this method of thread swallowing I have been able to relieve most desperate and apparently hopeless cases of multiple stricture both in children and adults, and keep them from living the rest of their lives dependent on a tube and tunnel in connection with a gastrostomy opening.

In conclusion let me strongly insist upon care and delicacy of manipulation in all esophageal work. Do not even examine too long at the first sitting if the instrument does not pass readily. Too prolonged probing may send the patient home with a stricture that is tightly closed by swelling, and the result may be serious. The esophagus is more intolerant of violence than even the urethra.

DISCUSSION.

DR. G. W. GAY of Boston: It has fallen to my lot to do esophagotomy four times: once upon a child three and one-half years of age, for the removal of a cent; once for a plate carrying four teeth; once for a fish-hook, and once for a malignant stricture of the esophagus to enable a Symond's tube to be placed in position. Another case of foreign body should have been treated by operation, but owing to one of those psychical lapses to which, I presume, most of us are occasionally liable, the diagnosis was not made until the autopsy revealed a small sliver which had ulcerated through the walls of the esophagus, and produced an abscess in the mediastinum. The first operation was done in 1878. No more cases came to my notice for thirteen years, when three operations were done within five months.

My first case of esophagotomy was done on Sunday, Sept. 8, 1878. The patient, a cook, forty-nine years of age, while eating fish, felt something lodge in the throat, which prevented her from swallowing solids. She entered the City Hospital twenty-six hours after the accident, presenting the usual symptoms of these cases. She was unable to swallow solid food, and could swallow liquids only in a very small quantity, and after repeated and painful efforts. She was weak, depressed and evidently the victim of a profound general disturbance.

The careful use of the bristle and sponge probangs failed to dislodge the foreign body. The pulse and temperature began to rise, and the constitutional disturbance, in the way of restlessness, depression and debility, increased. Forty-eight hours after the accident the esophagus was exposed upon the left side, as described by Dr. Cheever in his classical monograph. A sharp substance was felt at the bottom of the wound, which after a little manipulation was seized with forceps and made to cut its own way through the walls of the gullet, purulent matter escaping with it. The cause of the trouble proved to be a thin, flat fish bone an inch and a quarter in length and a third of an inch wide. It was imbedded in the posterior wall of the esophagus opposite the cricoid cartilage. No ligatures were required. The small wound in the esophagus was allowed to take care of itself. The external one was closed with sutures.

For four days after the operation no food or drinks were swallowed, but she received rectal injections of beef tea, etc., every four hours. The wound suppurated moderately, but no food or drink ever escaped from it. It was healed in ten days, and the patient left the hospital eighteen days after operation. She was able to eat solid food, and was apparently as well as ever.

This was a fortunate case in that the operation was done earlier than usual, — forty-eight hours after the accident, — the foreign body was located favorably for removal and comparatively little violence to the deeper structures was necessary.

Lena, three and a half years old, was brought to the City Hospital on Friday, October 16, 1891, with a history of having swallowed a foreign substance eight months before. She was said to have had little, if any, trouble for six months; but for the past two months she had ejected most of her food in about a minute after it was swallowed. She was weak, languid, emaciated and presented all the appearance of a sick child.

She was examined under chloroform with an ivory-tipped probang, and a metallic body readily detected in the lower part of the esophagus. The gullet was opened in the usual manner, the walls being divided upon a uterine sound as a guide. The foreign body was located about two inches below the top of the sternum and four inches from the opening in the esophagus. It was readily removed with a pair of bullet forceps, and proved to be an ordinary copper cent.

The wound was left open, and the child was nourished for some days on enemata of peptonized milk. From the first she was allowed to drink all the cold water she wanted, as the thirst was irresistible. Liquids escaped from the wound in diminishing quantities for ten days. The child was up and around the ward in thirteen days, and was discharged two days later. Twenty-five days after operation she was eating solids, had regained her flesh and strength, and was well.

A teamster, a young man of intemperate habits, fell from his cart and knocked a plate with four false teeth down his throat. He entered the hospital four days later in a wretched condition. He could swallow only liquids, and these in very small quantity, and with great difficulty. He was septic, weak, despondent and miserable.

With an ivory-tipped probang the plate was easily detected in the esophagus, thirteen inches from the upper incisors and about four inches below the top of the sternum. There was moderate swelling above the clavicles and sternum.

Esophagotomy was done at once, the walls of the tube being divided upon a pair of esophageal forceps used as a guide. The plate was located about seven inches from the wound, and after careful manipulation was finally removed with forceps. Its measurements were one and three-quarters by one and a half inches, with the usual sharp corners and prominent borders.

The wound was closed, and the patient fed and stimulated by the rectum and through a stomach tube. In spite of vigorous measures along these lines, he died of sepsis five days after the operation.

Mr. K., aged forty-eight years, entered the City Hospital suffering from a malignant stricture of the esophagus, which prevented his swallowing anything whatever. The dysphagia had been growing markedly worse for about four months. As might be expected, he was weak and emaciated, and suffering all the horrors of slow starvation. All instruments passed into the gullet brought up in a pouch behind the sternum. To enable a bougie to be passed through the stricture into the stomach, the esoph-

agus was opened in the usual place and manner, and with a finger in the wound a hard mass, the size of a hen's egg, was readily felt, involving the gullet. Above this mass the esophagus was dilated into a sac. On the anterior wall about an inch from the bottom was found the opening of the lower portion of the gullet leading to the stomach. A long bougie was passed through the mouth and, guided by the finger in the wound, was made to enter the lower part of the tube. This done, Dr. Mixter had no difficulty in placing the No. 19 Symond's tube in position, so that it passed through the stricture into the stomach.

The patient rallied well from the chloroform, and was able to drink liquids fairly well. While considerable quantities escaped from the wound, yet he retained enough to remove his hunger and thirst, and to enable him to gain quite a little strength, sufficient to make him much more comfortable than he was before the operation. The tube was replaced by another in two weeks, and again nine days later. As this last one could not be removed by any reasonable force, it was allowed to remain during the remainder of his life.

This patient improved sufficiently to enable him to go home a month after the operation, where he remained until two days before his death. He entered the hospital for the last time, emaciated to the last degree, and suffering horribly from dyspnea. A quick tracheotomy was done under a few whiffs of chloroform with some little relief, but he soon succumbed to the disease and died in forty-eight hours.

Could this patient's esophagus have been intubed earlier, it is but fair to conclude, from the relief he did get, and from the experience of Dr. Mixter and others, that he might have lived some time longer, and that he certainly would have suffered less than he did. In the earlier stages of the disease, before the esophagus had become dilated above the growth, the Symond's tube could probably have been inserted without any operation. This disease is always fatal so far as we know, and yet almost any measures are justifiable to give even temporary relief to the horrible suffering of slow starvation.

The diagnosis of foreign bodies in the esophagus is not difficult for those who have ever seen a case of this sort. Many physicians, however, have never met with the accident, and therefore might find it anything but easy to distinguish the real from the suspected cases. The latter are more common than the former, and usually occur in nervous or neurotic persons, as servant girls, etc. They complain of pain and difficulty in swallowing, and yet they can readily swallow liquids, or even solids, without any great effort. They are apt to be indefinite as to the exact location of the sore spot, it being situated in different places at different times, or more commonly the distress is a general soreness, rather than a distinct, localized, painful spot. There is no constitutional disturbance whatever, no increase in pulse or temperature, and no depression of the vital energies. They are nervous and frightened, but not sick.

Now, the clinical picture of a person with a foreign body lodged in the esophagus is very different from all this, and once seen can never be forgotten. Depressed, anxious, debilitated from the lack of nourishment, dreading to make the effort of swallowing, and accomplishing that function only with great difficulty and after repeated trials, locating the tender or painful point definitely, and always in the same place, — these symptoms point very strongly to the pressure of a foreign body in the gullet. The diagnosis is complete if it can be confirmed by an examination with an ivory-tipped bougie or similar instrument. Unfortunately many foreign substances elude the peculiar impact of the bougie, and thus little or no aid is to be obtained in that manner. The above symptoms, however, if severe and progressive, justify an exploratory operation.

The x-ray furnishes unmistakable evidence of the presence of certain substances in this part of the body, as well as in every other. False teeth, pins, needles and other metals are readily shown by these rays, and thus give us the benefit of a positive diagnosis.

Little dependence can be placed upon bristle and other probangs for the removal of foreign bodies from the gullet. They sometimes succeed but oftener fail in accomplishing the object. I once removed a large piece of turkey bone and meat with the bristle probang, twenty-four hours after its introduction. In a case of a child three and a half years old, a careful examination under chloroform failed to reveal any foreign body, although the symptoms pointed strongly to its presence. Operation was refused. Eight months after the supposed accident the boy vomited a pewter quarter of a dollar. All symptoms, including a persistent hoarseness, soon after disappeared, and the boy was perfectly well.

In regard to the method of doing esophagotomy the only point that I would call especial attention to is the use of some metallic guide in the esophagus. The great advantage of this sort of an instrument over a flexible one is that it can be more readily introduced, can be manipulated and controlled at will, and hence made prominent at place of incision of the esophageal walls. We have found the ordinary uterine sound to answer the purpose very well, especially in children, but anything having the necessary curves and stiffness will do.

In a thin neck, free from edema or swelling, the operation for opening the esophagus is not a difficult one, but under opposite conditions it may be very difficult. Hemorrhage usually gives little or no trouble, and often no ligatures are required. As a rule the writer has used chloroform in operations upon the esophagus, as well as in those involving the trachea, for the purpose of avoiding the spasm of the glottis and free accretion of mucus, which at times threatens to drown the patient. Less danger is to be apprehended from these complications in opera-

tions upon the esophagus than upon the trachea, in which they are common and call for close watching and prompt relief to avoid disastrous results. The risks in the use of chloroform under these circumstances are probably less than are to be expected from the various complications that may arise under ether. The writer has never met with any trouble or untoward symptoms from the use of chloroform in operations about the face and neck, while he is fully aware of the moderate danger of its use in general surgical operations.

INFERENCES TO BE DRAWN FROM THE EXAMINATION OF THE GASTRIC CONTENTS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

THE gastric contents are examined chiefly to aid in the diagnosis and treatment of catarrh, dilatation, ulcer, cancer and neuroses of the stomach or to obtain proof that it is in a healthy state. The list is a small one. In reality the diagnosis of the various diseases of the stomach is far easier than is usually thought. The rule of exclusion can be used to great advantage.

The data upon which diagnoses are based are also few, some six in number. Five of these can usually be detected by gross observation, while the chemical tests for the remaining are extremely simple. The subjects which admit of discussion to-day are: (1) Gastric motility. (2) Gastric secretion. (3) Gastric fermentation. (4) Mucus. (5) Blood. (6) Pus.

Another function of the stomach — absorption — is not included in this list. Absorption may be disregarded, because so little takes place through the walls of the stomach. Practically no water is absorbed. When water enters the stomach, it is either expelled through the pylorus, the cardiac orifice or remains. There are one or two exceptions to this rule of the non-absorption of food in the stomach. Sugar and peptones are absorbed to a slight extent, varying with the concentration of the solution. Alcohol is readily absorbed, as is manifested by clinical experience. When alcohol is absorbed from the stomach, water is secreted into it in more than equivalent volume. Since absorption is of such minor importance, the iodide test for it is superfluous.

(1) *Gastric motility.* — The power to expel its contents is the most important function of the stomach. If secretion utterly fails, there occurs only a moderate impairment of digestion. This is due to the compensatory action of other digestive organs. Let gastric motility fail, however, and distressing, urgent or fatal consequences invariably ensue.

Gastric motility is disturbed by various means. Perhaps the commonest is that due to weakness of the gastric muscles themselves. This may form part of a general muscular weakness, and is often associated with a displacement of the stomach and frequently of other organs. Such a displacement increases the work to be done by the stomach because the pylorus is more firmly fixed than the rest of the organ and the food must be raised before it is expelled. A vicious circle is the result.

Another cause less generally appreciated is interference with the continuity of the inner wall of the stomach. Such a state is brought about by an ulcer or cancer, even when they do not obstruct the pylorus. The interference with motility in such cases is not extreme, but it is quite constant. The detection of slight degrees of disturbed motility is therefore important and a suspicious sign.

Obstruction to the passage of food through the pylorus is the most obvious cause of disturbed muscular action in the stomach. At first the obstruction usually leads to extra efforts on the part of the muscle walls. This is apparent to the patient by the sensations produced and to the physician by his observance of peristalsis. In the advanced stages of this condition exhaustion of the muscles apparently succeeds to active peristalsis and the most extreme grades of dilatation of the stomach result. It is often impossible to determine the cause of a pyloric obstruction at a first visit and it is unwise to attempt a diagnosis. Repeated observation of the behavior of the stomach under varying conditions is essential. In many instances time alone will determine whether the stricture is functional, being due to spasm, or is organic from the presence of a scar, ulcer, cancer or other less common causes.

The determination of gastric motility is the most important test in the diagnosis and treatment of disorders of the stomach. Frequently proof of its derangement is afforded by the story of the patient. Food is vomited which has been eaten more than seven hours previously, or quantities of food are vomited which are so large that they are directly suggestive of a dilatation of the stomach. This is acute or chronic according to the frequency with which such vomiting has occurred. A degree of muscular disturbance sufficient to produce such symptoms is rare, but even when it occurs it is not uncommonly overlooked. It must not bias the practitioner, however, in favor of malignant disease any more than marked loss of weight in an individual with indigestion.

In contrast with this crude method of estimating gastric motility is the accurate test of this function by the passage of the stomach tube into the fasting stomach. The fasting stomach should be empty. If food is obtained from it seven hours after a meal it can be assumed that there is disturbance of gastric motility. This examination is the simplest and most valuable of all examinations of the stomach which are made. In the first instance, the manipulation of the tube is easier with the fasting stomach than after a test meal. In the next place, the contents so removed are more readily examined. Inspection alone will determine the presence of food, secretion, fermentation, mucus, blood and pus —

[1] Read before The Massachusetts Medical Society, June 9, 1903.

the essentials for gastric diagnosis. Too much cannot be said of the value of the examination of the fasting stomach.

Conclusions regarding gastric motility may be reached by measuring the quantity of food removed from the stomach one hour after the administration of an Ewald test breakfast. The slice and a half of bread and the glass and a half of water of which this consists should leave a residue of not more than 3 oz. when removed under the above conditions. Excess of this quantity suggests a deranged muscular activity. Another method of reaching the same result is to give Hemmeter's test meal. This consists of one small piece of beef (2¾ oz.), one soft boiled egg, 1 oz. boiled rice, one-half pint milk and a piece of bread. Four to five hours later an Ewald test breakfast is given and the contents removed in one hour. The complete disappearance of the earlier meal points to normal motility. Gastric motility has been tested in still another way by directing the patient to eat at night a few spoonfuls of dried English currants. These would not be found on the following morning in a healthy stomach.

Normal motility is present in two diseases of the stomach — gastric catarrh and in the group of cases included under the term "achylia gastrica." In the latter instance excessive motility has been supposed to be present. This idea may have arisen from the fact that undigested fragments of food are expelled with difficulty through the stomach tube. The stomach is then considered empty when this is really not the case. The water has passed on, but the solid particles of undigested food remain and can be obtained by prolonged expression, aspiration or lavage.

(2) *Gastric secretion.* — The healthy stomach produces about three pints of gastric juice in twenty-four hours. Ordinarily this passes on with the food into the intestine without causing disturbance. It is obvious, however, from what has been said of the slight degree of absorption which takes place in the stomach and the various conditions in which the muscular power of the gastric wall is affected, that such quantities of secretion can cause many symptoms. Much confusion exists between slight degrees of deficient motility and excessive production of gastric juice. But the pronounced states of either are clear. When the secretory function is in a normal condition the fasting stomach will be empty; if hypersecretion is present, varying quantities of gastric juice up to several ounces can be removed from the fasting organ. Increased secretion of gastric juice is pathognomonic of no single disease. It most frequently occurs as a neurosis in connection with an overproduction of hydrochloric acid. It is a precursor of ulcer of the stomach and is the signal for prophylactic treatment. It accompanies ulcer.

The constituents of gastric secretion which are most important for recognition are hydrochloric acid and pepsin. Their presence in normal quantities may be inferred with great probability from the gross appearance of an Ewald test breakfast. Such contents removed from a normal stomach look "well digested." If gastric secretion is absent the contents resemble closely a mixture of bread and water. It is not safe, however, to rely wholly on gross appearances, for occasionally with excessive amounts of hydrochloric acid a somewhat similiar condition is produced.

The safest test for hydrochloric acid is with Günzburg's reagent.[2] This is performed by slowly heating a few drops of this solution with an equal amount of the stomach contents. A red color develops. Another test is with Congo red paper.[3] This turns blue when moistened with a solution containing free hydrochloric acid. The development of a brownish color with Congo red denotes the presence of some organic acid. Congo red paper is very useful in a general practice because it requires no apparatus. Following a suggestion of Dr. Pfaff, it can be prepared in different strengths, and with these an approximate idea of the percent of free hydrochloric acid in the stomach can be obtained.

Excess of hydrochloric acid occurs most commonly as a neurosis. It is the torment of the nervous dyspeptic and the nervously tired-out individual. Like hypersecretion it frequently precedes ulcer of the stomach and generally accompanies the condition when established. Often hyperchlorhydria occurs in dilatation of the stomach due to a benignant stenosis of the pylorus. In such cases the stagnant food appears to call it forth. Ulcer is usually associated with the presence of free hydrochloric acid, often in excessive amounts. In cancer, free hydrochloric acid is the exception. It is by no means seldom, however, that a chronic ulcer exists without free hydrochloric acid and that a cancer is accompanied by free hydrochloric acid. In the latter instance the cancer has usually developed from an old ulcer — a much rarer condition than supposed.

The hydrochloric acid is diminished in catarrh of the stomach to a greater or less extent according to the severity of the disease. It is completely absent in atrophy of the mucous membrane and sometimes absent when no atrophy exists, perhaps due to a secretory neurosis. Patients in whose gastric contents no hydrochloric acid can be found after repeated trials are said to have achylia gastrica. (Strictly speaking, the absence or marked diminution of pepsin and renin also should be proven to establish this condition.) The acidity of such contents hardly suffices to react red with litmus. The gross appearance of an Ewald test breakfast removed from a patient with achylia gastrica

[2] Günzburg's Phloroglucin-Vanillin Test.

Phloroglucin	2
Vanillin	1
Alcohol	30

[3] Filter paper saturated with aqueous solutions of Congo red of the following strengths will react with the given percents of free hydrochloric acid:

Congo Red.	*Hydrochloric Acid.*
Percent.	*Percent.*
0.001	0.200
0.00175	0.150
0.0025	0.075
0.0062	0.050
0.01	0.025
0.05	0.01

resembles a mixture of bread and water, so incomplete is its digestion. It is a rule for the hydrochloric acid to be absent in cancer.

Pepsin varies in the gastric juice to a greater or less extent with the hydrochloric acid. In most examinations of the stomach contents the tests for it can be omitted. It can be demonstrated as follows: Add a portion of the white of a hard-boiled egg of about the size of a dime to 2 dr. of filtered gastric juice. Keep at body temperature. The egg normally is digested or disintegrated in two to six hours. If free hydrochloric acid is not present, add dilute hydrochloric acid one drop at a time until its appearance is shown by Günzburg's or the Congo red test.

(3) *Gastric fermentation.* — Fermentation in the stomach is proof of diminished motility. It is recognized by the appearance of three layers in the gastric contents, which form about a quarter of an hour after their removal. This is best shown by placing the contents in a glass. The lower layer consists of partially digested food, the middle layer is liquid and contains the soluble products of digestion, while the upper is frothy, due to the admixture of gas (chiefly carbonic acid) with small particles of food. The exciting agent of the fermentation varies, and, as Dr. Hewes has shown to the students of the Harvard Medical School this year, can be isolated. Especial interest attaches at present to but two sorts of fermentation — that caused by sarcinæ and that due to the lactic acid bacillus. Sarcinæ grow abundantly in the presence of hydrochloric acid, and lactic acid bacilli only in its absence. The presence of sarcinæ therefore implies fermentation in a stomach which is still secreting hydrochloric acid, while lactic acid implies that no hydrochloric acid is being produced. In both, motor insufficiency is present. Sarcinous fermentation has a peculiar odor which is so distinctive that when once appreciated it is easily recognized. The sense of smell alone can in this way lead to a conclusion that hydrochloric acid is present. Conclusive proof is afforded by the detection of the "cotton-bale" shaped sarcinæ under the microscope. Lactic acid is demonstrated by the distinct appearance of a canary yellow color on the addition of filtered gastric contents to a nearly colorless solution of ferric chloride. The demonstration of sarcinæ or lactic acid in a stomach contents adds therefore nothing new to our knowledge. It is simply another method of showing that a state of deficient motility, associated with or without hydrochloric acid, exists.

(4) *Mucus.* — Mucus is present in the stomach when there is catarrh of that organ. Acute or chronic gastric catarrh exists only when associated with mucus. The acute cases attract little attention, for the duration of the disease is so short that an examination of the stomach is seldom necessary. Chronic catarrh of the stomach is a rare disease, notwithstanding it is so common in the minds of the laity, and for that matter in the diagnoses of the profession. In a recent four months' out-patient female medical service in which about one thousand new patients were seen, only one typical case of chronic gastric catarrh was recognized. In fact, one of the decided advantages of the examination of stomach contents is the opportunity it affords of disabusing the patient's mind of the idea that he or she has a chronic catarrh. On the other hand it must be remembered that catarrh may exist with cancer or dilatation of the stomach. The mucus obtained from the mouth, throat and esophagus during the passage of the stomach tube should always be distinguished from mucus formed in the stomach. Gastric mucus is intimately mixed with the food; other mucus is not. Mucus is most easily detected in the fasting stomach.

(5) *Blood.* — Blood is not uncommonly obtained from the fasting stomach. Cancer is the disease most uniformly associated with it, for either a little blood is present in the stomach before the introduction of the tube or is set free by the irritation of the tube itself. Ulcer behaves similarly. Very small quantities or little clots of blood are frequently obtained from patients with achylia gastrica. These three diseases can often be differentiated by the state of gastric motility and the hydrochloric acid. Blood may also be obtained from the healthy stomach by too forcible straining and struggling on the patient's part or too powerful aspiration of the contents by the doctor. Coffee-ground vomitus perhaps is more commonly associated with cancer than with ulcer, but it is by no means proof of it. It may occur daily for a week in ulcer.

(6) *Pus.* — Pus is common in any gastric catarrh. It is frequently met with in the fasting stomach of patients with cancer or ulcer, and so in the absence of mucus gives valuable evidence.

Diseases of the stomach can be treated empirically or with a certain degree of scientific accuracy. The scientific method is usually successful, while empiricism favors a migratory tendency on the part of the patient. If, on the other hand, empiricism is successful and the patient is cured, in the end more real harm results, for the doctor is encouraged to repeat his lucky experiment and his medical progress thereby comes to an end.

The examination of gastric contents is often neglected because it is thought to be too difficult and too time-consuming. These views are erroneous. The examination requires no more time than the examination of the urine, and is far simpler. In fact, the gross examination of the gastric contents furnishes the most valuable data of all, and these can be recognized almost at a glance. There is no necessity for the busy practitioner to titrate the percent of hydrochloric acid in the gastric contents. It is far more important that he should determine whether the organ contains food and secretion in the fasting condition and that he should make the simple tests necessary for their examination. More important still is the need for a proper interpretation of the results so obtained.

Rules are no more hard and fast in this branch

of medicine than in any other, and satisfactory deductions can only be drawn when the history of the patient, the physical signs and the data relative to the contents of the stomach are considered together.

DISCUSSION.

DR. R. F. CHASE of Brookline: Dr. Joslin has very thoroughly and concisely discussed a very broad subject. He has left very little to be said upon this subject. There are, however, a few points to which I wish to refer with the object mainly of emphasizing their importance:

When a patient comes to the physician for an examination of the stomach, he should not have eaten anything for at least six hours.

With a fasting stomach the physician can at once proceed to give a test meal and later examine the gastric contents obtained therefrom. Or, should it seem preferable, he can obtain the fasting contents (if there are any), then inflate and determine the size and position of the stomach.

Either part or the whole of such an examination may be made at the first visit, providing the patient comes with a fasting stomach. Whereas if he comes with a full stomach none of these tests can be conveniently carried out at the first visit. Dr. Joslin has already said that several examinations may be necessary to establish a diagnosis.

I particularly desire to emphasize the importance of this point, because I know there are physicians who have the impression that one chemical examination of the gastric contents is sufficient to enable one to make a diagnosis of any gastric affection. Such, however, is not the case. Besides the chemical examination of the gastric contents, the size, shape and motility of the stomach must be determined in all cases, and in many cases new phases of a disease appear which require prolonged study that they may be recognized and properly treated.

The average amount of gastric contents obtained one hour after the administration of an Ewald test meal has been stated by the reader as 90 cc., or 3 oz. I consider this amount a very fair average, but one must remember that it is only an average, the maximum and minimum normal limits being very wide, varying from about 20 to 150 cc.

A healthy student upon whom I recently made some tests yielded, on several successive days, from 120 to 160 cc. of gastric contents. On a certain day preceding a school examination which he was to take, I was able to obtain only 10 cc. one hour after the Ewald meal, and this gastric juice contained no free HCl, whereas on the previous examinations the free HCl had always been normal. This temporary suppression of the gastric secretion I attributed solely to nervousness arising from anxiety over his pending school examination.

Small amounts of gastric contents are obtained in the conditions referred to by Dr. Joslin, namely, in diminished secretion, in hypermotility of the stomach and in cases of patent or lax pylorus.

In these conditions it is frequently, I may say usually, necessary to introduce the stomach tube within thirty or forty minutes after giving the Ewald meal, to obtain any contents for examination.

Failure to obtain the average amount of gastric contents one hour after the Ewald meal does not necessarily indicate the existence of one of the conditions just mentioned; it may mean that the entire contents of the stomach have not been removed.

Lavage of the stomach will clear up this point, because if the contents have not been entirely removed crumbs of bread and cloudiness of the wash water will be observed. Formerly I used (as recommended by some) a Davidson's syringe bulb in evacuating the stomach contents and in 20 to 30% of all cases I obtained small amounts of blood. I now use a different bulb, and do not encounter blood in more than 2 to 4% of all patients. Small amounts of blood, however, are frequently of no significance.

Mucus must *not* be confounded with saliva, which as a rule runs freely down the *outside* of the tube. The former is recognized by its stringy nature and comes of course only from the *inside* of the tube; it is also well seen when pouring the contents from one vessel into another.

Excepting the detection of blood, or food which has been eaten one or two days previous, an examination of the vomitus from a patient does not aid one much in the diagnosis of gastric disease.

Dr. Joslin has stated that during a three months' hospital service he has failed to encounter one case of chronic gastritis.

During a present ten weeks' service I have also not met one case of chronic gastritis. This disease of the stomach, of which we hear so much, is not nearly so common as is generally supposed.

New Instrument.

A CHEAP TRACTION SPLINT.[1]

LOUIS T. WILSON, M.D., BOSTON.

THIS splint was made primarily to fill a need for a cheap, light splint suitable for bed traction on hip cases at the Children's Hospital, Boston. The average hip splint is heavy, requires a skilled mechanic to manufacture it, is therefore costly and thus often beyond the reach of the physician, outside the large cities, who may have hip cases under his care. It was desired, therefore, at the same time, to make a splint of such simple construction and material that it could be easily made by any mechanic, blacksmith or even the physician himself if necessary, at a very small cost. Sheet steel and gas-pipe can be easily obtained in almost any town, and from these materials this splint was made.

[1] Presented at the Annual Meeting of the American Orthopedic Association, Washington, D. C., May 14, 1903.

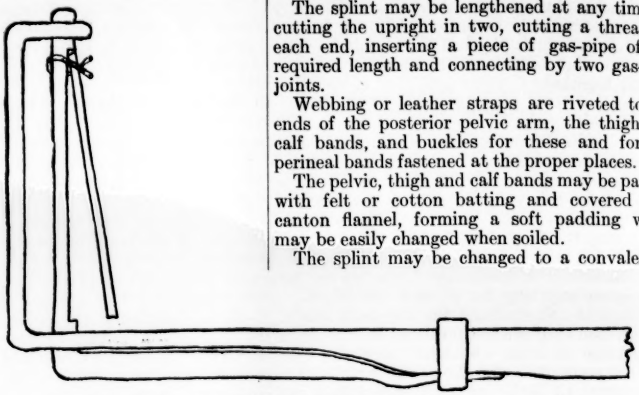

FIG. 3. — TRACTION WINDLASS AND FOOTPIECE.

The upright and foot piece are made from one piece of $\frac{3}{4}$-inch iron gas-pipe. The upright, where it joins the pelvic band, is simply heated and flattened for a distance of about one inch. The lower end forming the foot piece is also heated, flattened and bent to the desired shape. Care should be taken to flatten the pipe for a distance of three to four inches up on the upright to allow a flat surface for the windlass arm.

The traction windlass is made from $\frac{1}{8}$-inch steel wire bent to a right angle. One arm is inserted into two holes bored in the foot piece, while the other lies along the upright, which was flattened and is held to it by a sliding wire ring. The traction windlass may be prepared to hold the extension straps in one of three ways: (1) A slot may be cut in the wire, the straps passed through and caught by a turn of the windlass. (2) Two small wire pegs may be inserted into the wire to fit into holes made in the straps. (3) The wire may be filed flat on one side where it crosses the foot piece, and a flat piece of steel fitted to this. The extension ends are then laid on the flat wire, the steel placed on top and caught at one end by a turn of fine wire. One turn of the windlass arm binds these together and prevents any further slipping.

The pelvic band is cut from sheet steel of the desired gauge (generally No. 10–No. 14), riveted on to the flattened end of the upright and bent to the desired shape. In the large splints it may be necessary to secure a firmer hold on the upright, in which case a tab of steel may be left on the band and this bent around to grasp the upright. Also the arms of the first pelvic band may be made only two or three inches long and a second pelvic band of the required length riveted to this. This gives a firmer band and prevents the perineal straps, when tightened, from drawing the arms together.

Thigh and calf bands are cut from thin sheet steel and fastened to the upright by boxes made from similar steel and riveted to the bands.

The splint may be lengthened at any time by cutting the upright in two, cutting a thread on each end, inserting a piece of gas-pipe of the required length and connecting by two gas-pipe joints.

Webbing or leather straps are riveted to the ends of the posterior pelvic arm, the thigh and calf bands, and buckles for these and for the perineal bands fastened at the proper places.

The pelvic, thigh and calf bands may be padded with felt or cotton batting and covered with canton flannel, forming a soft padding which may be easily changed when soiled.

The splint may be changed to a convalescent splint by removing the foot piece and substituting a piece of gas-pipe ending with a joint into which a piece of rubber or a rubber cork has been inserted.

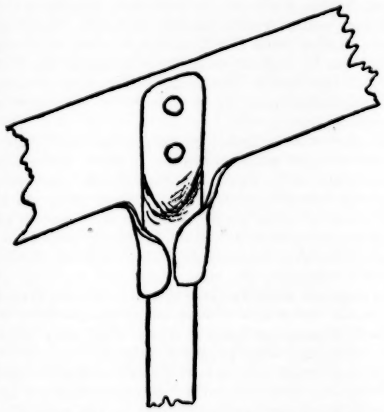

FIG. 1. — METHOD OF FASTENING PELVIC BAND AND UPRIGHT.

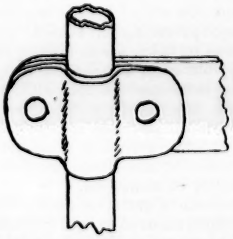

FIG. 2. — METHOD OF FASTENING CALF AND THIGH BANDS TO UPRIGHT.

This splint has been in use in the wards and on young children in the Out-Patient Department of the Children's Hospital, Boston, since March and so far has proved satisfactory. The cost as made in the hospital shop ranges from two dollars and a half to three dollars and a half. Of this, the material costs seventy-five cents to a dollar according to the size. The weight of a 30-inch splint is about eighteen ounces.

Medical Progress.

PROGRESS IN THORACIC DISEASE.

BY JOHN W. BARTOL, M.D., BOSTON.

INFLUENCE OF WIND ON PHTHISIS.

GORDON[1] has studied the distribution of phthisis in certain districts of Devonshire, and concludes that there is justification for the belief that strong, wet winds, when prevalent, have a marked influence in raising the death-rate from phthisis in communities exposed to them, and that this effect is possibly explained by the chilling and depressing nature of the winds and their tendency to excite bronchial catarrh in the inhabitants of such districts.

CONSUMPTIVE CHEST NOT FLAT.

Hutchinson[2] has followed up his preliminary investigation published in 1897, and feels more than ever convinced that the tuberculous chest is round rather than flat, or in other words that prevailing belief and teaching is entirely erroneous. The human chest, with a few exceptions easily accounted for, is the only one in the animal kingdom in which the transverse diameter is the longer, a relation obviously explained by the erect position and the locomotive necessities of the anterior limbs. Measurements taken of series of normal chests show the index of proportion of antero-posterior diameter to transverse to be approximately 70%; in the embryo the index runs up to 105–115, while at two years it is about 94, and from three to seven averages 85. In the tuberculous chest the average of the measurements thus far taken is not far from 80, or, in other words, a persistence of the type normal for the age of fifteen to eighteen years. The apparent flatness of tuberculous chest is an optical delusion due to the condition of round shoulders, and this in turn is the result of the forward displacement of scapulæ on a thoracic wall which is barrel-like instead of flat.

Conclusions of importance are that the existence of such a conformation in a person past the age of eighteen is a sign of arrested development; that it is likely to be precedent to tuberculosis; that systematic measurements should be made in growing children, and flatness of chest favored by appropriate exercises.

TRAUMATIC PERICARDITIS, ENDOCARDITIS AND MYOCARDITIS.

Pleasants[3] concludes that trauma is a much more important cause of disease of the heart than is generally supposed. Judging from the frequency with which pericarditis of any origin is overlooked, he thinks that the traumatic form exists many times unrecognized, and publishes two cases of his own, in one of which the somewhat startling assumption of injury by *contre-coup* is made. Endocarditis definitely shown to have developed in connection with serious injury to the thorax has occurred in one case of his own knowledge and in three other cases from the literature, and it is considered probable that in many instances an endocarditis developing some little time after an injury without other discoverable cause is due to the trauma. A myocarditis set up by trauma in a previously normal heart probably does not attain a development sufficient to cause signs capable of demonstration, and if the heart was previously diseased, a supposed relationship between trauma and myocarditis must be very carefully probed before it is accepted as proven. Altogether five cases are reported which are considered above suspicion.

TIDAL PERCUSSION.

Colbeck[4] complains not only that too little attention is paid to percussing the apices during both inspiration and expiration, but that a mistaken belief in regard to percussion changes produced by this maneuvre is very prevalent; in other words, contrary to general belief and for manifest anatomical reasons, there is above the clavicles in full inspiration a decrease in the limits of pulmonary resonance and in full expiration an increase of the same, while during the same intervals there is respectively a raising and lowering of percussion note. Investigations bearing on this point were reported eighteen months ago, and further study has simply served to confirm the opinion then formed.

LATE SYSTOLIC MITRAL MURMURS.

Hall[5] considers that, when the murmur of mitral incompetence occurs not with but later than the first sound, there exists a marked degree of asynchronism, that the first sound is due to the earlier contraction of the right ventricle and that the later contraction of the left gives not a sound but a murmur. In some cases, however, he grants that the delay may be an apparent one due to the first part of the murmur being inaudible, and also admits as a possible factor the pulling in of the auriculo-ventricular curtains by the contraction of the papillary muscles, shown by Roy and Adami to be the final act in ventricular contraction.

DIASTOLIC MURMURS WITHOUT LESIONS.

In a series of one hundred and fifty-three autopsies studied with relation to mistakes in physical diagnosis Cabot and Locke [6] found "not a single case in which a diagnosis of aortic regurgitation made during life failed to be substantiated at autopsy," but they are able to report four cases seen within a year in which the demonstration of normal aortic valves discredited the probable diagnosis of aortic regurgitation, based on the presence of a diastolic murmur. Similar instances have been reported by various observers and sundry explanations offered. Of these the most plausible are taken to be: (1) Dilatation of the aortic ring associated with aneurism or diffuse enlargement, or dependent on high blood pressure; (2) tuberculosis of the lungs and pleura, and consequent production of cardio-respiratory murmur; (3) intense anemia, with the relation of thinness of the blood to the production of murmurs still unexplained.

CARDIAC HYPERTROPHY IN NEPHRITIS.

Senator [7] returns to this unsolved question, and endeavors to explain why there is cardiac hypertrophy at all and also why it should especially affect the left ventricle. The investigations of Strauss carried out in his clinic show that there are marked differences between the blood in chronic parenchymatous and that in chronic interstitial nephritis. In the latter is found almost always an increased molecular concentration, an ordinarily normal specific gravity and albumen content, and an increase in the nitrogenous residue (that is, after precipitation of albumen), with consequent increase in the toxicity of the blood — while in the former, concentration is normal, albumen and specific gravity are lowered, and nitrogenous residue not increased. As a result of the toxic matters in the blood not eliminated on account of disease in kidneys, we get changes in the blood vessels with resulting symptoms, varying according to the nature of the process in the kidney. In acute nephritis the irritative effects are most marked — the walls of the vessels very rapidly lose their tone and dropsy ensues at once, and is protective in the sense that it helps remove from the blood the irritating elements; while duration is too short to produce permanent changes in vessel wall or heart. In chronic parenchymatous nephritis the poison works more slowly, the dropsy develops later, and the toxic effect on the heart muscle is gradually shown by hypertrophy; that this hypertrophy becomes so much more marked on the left is because peripheral resistance due to diseased vessel walls is so much more an important factor in the greater circulation than in the lesser. In chronic interstitial nephritis the toxic elements accumulate much more slowly, the vessel wall does not lose its tone, dropsy develops slightly if at all and there ensues the gradual changes in vessel walls and heart with same reason for a preponderance of hypertrophy of left ventricle. In this form of nephritis, however, where the initial renal insufficiency remains for a long time so slight and the consequent accumulation of poison is so slow, it is perhaps necessary to assume some toxic influence within the system independent of the kidney as a starting point for the disease.

INFECTIVE ENDOCARDITIS TREATED BY RECTAL INJECTIONS.

Duckworth [8] reports one case in which without much doubt of the diagnosis, and after internal treatment with fresh yeast and subcutaneous injection of antistreptococcus serum twice repeated had failed to produce any satisfactory effect, regularly repeated rectal injections of mixed antistreptococcus serum, 10 cc. at a dose, apparently effected a cure.

Reports of Societies.

SURGICAL SECTION OF THE AMERICAN MEDICAL ASSOCIATION.

NEW ORLEANS, LA., MAY 5 TO 8, 1903.

JAMES E. MOORE, M.D., President.

FIRST DAY — AFTERNOON SESSION.

H. J. WHITACRE, Cincinnati, read a paper entitled

SUPPRESSION OF URINE; REPORT OF A CASE ENDURING EIGHT DAYS, RELIEVED BY DECAPSULATION OF THE KIDNEYS.

The case was that of a woman aged forty, who took ergot for the purpose of producing abortion. The effect was entire suppression of the urine. She was taken to the hospital, and about 60 oz. of salt solution injected intravenously, with the result that about 5 oz. of urine containing albumin, casts and pus were passed on the third day. The kidneys were incised and decapsulated. The patient left the hospital on the nineteenth day, and nine weeks afterward was perfectly well, and excreting 60 oz. of urine per day.

DR. ALEX. HUGH FERGUSON, Chicago, read a paper entitled

THE SURGICAL TREATMENT OF NEPHRITIS,

in which he stated that he had published an article on this subject about one month prior to the appearance of Edebohls' first article. He reported two cases. The first case occurred in a young man twenty-four years of age, who died three and one-half years after the operation of removal of part of the kidney and decapsulation. He also reported a case suffering from pain in the loins, albuminuria, anasarca and ascites. He had contracted syphilis seventeen years previously, for which he had received mercurial

inunctions. At the time of his admission to the hospital his urine contained 5% albumin. The right kidney was decapsulated, and he left the hospital on the eighth day with only ½% of albumin in his urine. Later he returned for operation on the left kidney, the albumin having increased to 2¾%. He made a good recovery and the albumin has been reduced to $\frac{3}{10}$%.

DR. ARTHUR DEAN BEVAM, Chicago, felt that the value of surgical interference in the treatment of anuria had not been sufficiently emphasized. He divided the condition under three headings for the purpose of treatment: (1) Obstructive anuria; (2) reflex anuria; and (3) nephritic anuria. He preferred nephrectomy to decapsulation of the kidney for the treatment of anuria.

DR. WM. R. JEPSON, Sioux City, Iowa, thought that decapsulation of the kidney would be of little value in cases of chronic nephritis, and that it would do the greatest good in interstitial nephritis, with involvement of the surrounding structures and thickening of the capsule, especially where there is hemorrhage under the capsule.

DR. ARCHIBALD MCLAREN, St. Paul, Minn., felt that the benefit produced in these cases was probably more from the splitting of the kidney than from the decapsulation.

DR. RAMON GUITERAS, New York, said that the operation for decapsulation for Bright's disease was still in its infancy, and that the chief object thereof was to establish an increased circulation in the kidney. He stated that in the records of the autopsies of five hundred cases of chronic Bright's disease, he had found only one case of the pure unilateral variety.

DR. A. H. MCARTHUR, Chicago, reported a case of chronic Bright's disease of both kidneys, proven so to be by segregation, in which he had decapsulated both kidneys, one three months after the other, with decided improvement. During the time between the operation on the first and the operation on the second kidney, the difference between the excretory powers of the kidneys was quite marked.

DR. JOHN R. WINSLOW, Baltimore, Md., reported the case of a young woman who was in a septic condition following confinement, and suffered from pain over the right kidney and pus in the urine. Exploratory operation not revealing a condition that seemed to justify removal, the kidney was decapsulated and punctured, and the patient made a good recovery.

DR. ALEX. HUGH FERGUSON, in closing, referred to the almost instantaneous effect produced in some of these cases, the cause of which he attributed to the relief of the tension in the acute and subacute cases and to the improvement in the circulation in the chronic cases where the kidney had become contracted.

DR. H. J. WHITACRE, in closing, stated that there were various causes producing the condition of suppression of the urine, and believed that it was in those cases resulting from tension, produced by contraction of the capsule, that decapsulation would be of the most value.

DR. B. B. DAVIS, Omaha, Neb., read a paper entitled

INDICATIONS FOR CHOLECYSTECTOMY,

in which he reported twenty-eight cases upon which he had performed this operation, all but 20% of which were entirely cured.

DR. F. A. DUNSMOOR, Minneapolis, Minn., read a paper entitled

THE CALL FOR EXPLORATORY OPERATION IN THE GALL-BLADDER REGION,

in which he urged the value of this method as a diagnostic aid, and also its value in cases where operable conditions were not discovered, reporting two cases in which an exploratory laparotomy and breaking up of adhesions, etc., had been followed by recovery.

DR. WILLIAM J. MAYO, Rochester, Minn., emphasized the necessity for frequent operations upon the gall bladder.

DR. J. B. MURPHY, Chicago, recommended the removal of the gall bladder, unless this procedure was contraindicated, as we would thus remove the two chief causes of recurrence, namely, remaining stones and affections of the cystic duct; but owing to the high mortality following radical operation when infection was present, he felt that it was better to do as little surgery as possible to establish drainage under these circumstances,

DR. A. J. OSCHNER, Chicago, referred to the fact that many cases of gall-bladder disease were not diagnosed, and that more frequent exploratory laparotomy would be of material benefit in this respect.

DR. B. B. DAVIS felt that in those cases in which the condition of the patient was such as to render dangerous the removal of the gall bladder, one should first relieve the acute trouble and then do a cholecystectomy as a secondary operation. He believed that most of the cases of gallstones, if operated on early, could be cured without the removal, but in the complicated cases this procedure was necessary.

DR. F. A. DUNSMOOR, in closing, remarked that when the surgeon attempts to operate on the gall bladder he should be prepared to relieve any condition that may present itself.

SECOND DAY — MORNING SESSION.

DR. VAN BUREN KNOTT, Sioux City, Iowa, read a paper entitled

A CONTRIBUTION TO THE SURGERY OF GASTRIC ULCER,

in which he referred to the fact that about 80% of all gastric ulcers were situated on the posterior surface of the stomach or at the pylorus, thus bringing them in more or less direct contact with the liver, spleen, pancreas, intestines and other abdominal organs, the area of the adhesions and the extent of the intestinal wall infected vary-

ing considerably. Surgical interference was believed to be the only relief for these conditions, and gastro-enterostomy was recommended whether the adhesions be divided or not. Cases were reported bearing out the theories advanced in the paper.

DR. H. D. NILES, Salt Lake City, Utah, read a paper entitled

SURGICAL CONCEPTION OF PYLORIC OBSTRUCTION,

in which he recommended that if the growth be of a cancerous variety it be excised, as the pyloric carcinoma is slow to extend to surrounding tissues, but for the treatment of gastric ulcer he recommended gastro-enterostomy, owing to the likelihood of there being numerous ulcers.

DR. A. J. OSCHNER, Chicago, Ill., read a paper entitled

CLINICAL OBSERVATIONS ON THE SURGERY OF THE STOMACH,

in which he recommended that in all cases of gastric ulcer which did not heal promptly under medical treatment surgical treatment should be instituted, one of the most valuable methods being anastomosis between the lowest portion of the stomach and jejunum, a method which he thought reduced the persistent vomiting to a considerable degree. Three points in making the anastomosis by means of the Murphy button were emphasized: (1) The button must grasp just enough tissue to make a perfect union; (2) it must be at the lowest point; (3) there must be no tension.

DR. WILLIAM J. MAYO, Rochester, Minn., remarked that the surgical treatment was more particularly directed to the complications of gastric ulcer than to the ulcers themselves, and referred to the difficulty of knowing the best mode of procedure if the case was diagnosticated early, for if excision of the ulcer be performed, there is a liability that other ulcers will remain to give trouble afterward.

DR. CARL WAGNER, Chicago, reported the case of a woman who was suffering from a tumor in the center of the stomach about the size of two fists, which had been diagnosed by several surgeons as gastric carcinoma. Exploratory incision revealed that it was simply a mass of the omentum adherent to the parietal peritoneum, liver and gall bladder, and a tumor of similar formation was found in the inguinal region. Both were removed and the woman made a good recovery.

DR. WILLIAM L. RODMAN, Philadelphia, referred to the necessity for extreme caution in separating gastric adhesions, owing to the liability of tearing the stomach wall.

DR. A. H. CORDIER, Kansas City, recommended gastro-enterostomy in preference to excision of the ulcer, since it avoided the cicatricial tissue, which is the primary source of many ulcers.

DR. KNOTT, in closing, merely emphasized the necessity for prompt diagnosis and operative treatment in these conditions.

DR. NILES, in closing, stated that his reason for preferring gastro-jejunostomy was that he believed the ulcers would get well in almost any stage if the stomach were put at rest, which was done by this method, and in excision there was great liability of leaving some behind.

DR. OSCHNER, in closing, stated that he felt that with early recognition of the cases, pylorectomy would become a more favorable operation than it had been in the past. Precaution should be taken to prevent hemorrhage and the gastro-hepatic omentum should be removed.

DR. O. BEVERLY CAMPBELL, St. Joseph, Mo., read a paper entitled

THE SINGLE CUFF METHOD OF CIRCULAR ENTERORRHAPHY; A NEW METHOD,

in which he described in detail the technique of the operation, which he had performed on seventy-five dogs and two human subjects; seventy-two of the dogs recovered and none of the deaths was attributed to the operation *per se*. One of the operations on man was done after the removal of an adeno-carcinoma from the vicinity of the sigmoid flexure, and the patient made a good recovery. The second case was the resection of six inches of the bowel for a chronic fecal fistula following operation five months previously for obstruction of the bowel. Death ensued in thirty-six hours, and was attributed to the previous condition of the patient.

DR. JAMES H. DUNN, Minneapolis, Minn., read a paper on

INTESTINAL RESECTION, WITH REPORT OF FIFTEEN CASES, NINE WITH THE BUTTON AND SIX WITH SUTURE,

in which he stated that the Murphy button should be used except in cases of end-to-side anastomosis between the large and the small intestine, in which he recommended the employment of the Connell suture, the advantages being that it is simple, continuous and penetrates all the coats, thus insuring the strongest possible union. He emphasized the importance of selecting one method of suture, becoming expert in its use and adhering to it.

DR. J. B. MURPHY, Chicago, believed that a careful recognition of the pathological condition above and below the line of approximation was of more value than the technique of approximation, and believed that fewer failures would result if sufficient of the proximal end of the bowel were removed to leave a perfectly healthy, uninfiltrated intestinal wall.

DR. ALEX. HUGH FERGUSON stated that he had employed almost entirely of late the Connell suture and the Murphy button.

DR. CAMPBELL, in closing, stated that as the sutures did not go through the mucous membrane, he felt that the knots would do but little harm.

DR. JOHN A. WYETH, New York, read a paper entitled,

THE TREATMENT OF VASCULAR TUMORS BY THE INJECTION OF WATER AT A HIGH TEMPERATURE, WITH SUGGESTIONS AS TO ITS EMPLOYMENT IN TUBERCULAR ADENITIS, ABSCESS, FISTULOUS TRACTS, ETC.,

in which he stated that these tumors were chiefly of three kinds — arterial, capillary and venous, the capillary being the most numerous, and that under these conditions he had found injections of boiling water the most efficacious. He reported two cases in the first of which danger of hemorrhage prevented the removal of the growth by means of the knife, but it was successfully removed by this method. The other was a case of arterial angioma. Both operations were done under ether and both were entirely successful. The treatment was recommended in cases of hemorrhoids and fistulæ, and the only objection seemed to be the possibility of embolism.

DR. WM. J. MAYO, Rochester, Minn., stated that after seeing Dr. Wyeth perform this operation on one of the cases reported, he had injected ½ oz. of hot water into a large venous angioma of the cheek, with the result that in two or three weeks it was decreased in size two-thirds, and is now almost entirely gone.

DR. JOHN P. LORD, Omaha, Neb., reported a case similar to that referred to by the last speaker, which had been treated by electrolysis for some time without apparent effect. He then began treatment of the tumor by means of injections of iodine, the circulation in the surrounding vessels being cut off by finger pressure in order to avoid the chief cause of accident,— embolism,— and excellent results followed.

DR. RICHARD H. GIBBONS, Scranton, Pa., felt that this method would be of value in a great many inoperable cases of angioma, and suggested its use in fibroid and other tumors of the uterus.

DR. WYETH, in closing, stated that in all cases where surgical relief was possible, the knife should be employed. In regard to whether or not a thermometer could be attached to the syringe, he felt that the operation must be done too speedily to make this practicable.

FURTHER EXPERIENCE WITH THE VERTICAL OVERLAPPING OPERATION FOR THE RADICAL CURE OF UMBILICAL HERNIA,

was the title of a paper read by DR. W. J. MAYO of Rochester, Minn., in which he called attention to the difficulty of performing this operation successfully in adults, owing to their frequently obese condition, the attenuated abdominal muscles and the fact that the recti muscles are about three-quarters of an inch apart in this region, which is further accentuated by the downward strain present in most cases. The author now advocated, in order to cover the defect, the overlapping from above downward of the aponeurotic structures, which would secure a wide area of adhesion in place of an edge-to-edge union.

DR. A. J. OSCHNER, Chicago, referred to the fact that nearly every textbook on surgery gave for the radical cure of this condition a large mortality and a large percentage of recurrences. This he attributed to the fact that the operation was improperly done.

DR. J. B. MURPHY, Chicago, referred to the dangers from pulmonary edema when the lateral operation is done, because the sutures incapacitate the patient from diaphragmatic breathing; this is avoided by the method recommended by Dr. Mayo, and the opinion was expressed that with the employment of this method there would not only be a decrease in the mortality but a smaller percentage of recurrences.

DR. ALEX. HUGH FERGUSON, Chicago, while not recommending the abandonment of the lateral operation altogether, highly commended this mode of procedure. He thought that by cutting through the transverse fascia one could shorten the peritoneal muscles, and then stitching the sheaths of the muscular tissue one could make a good muscular union.

DR. MAYO, in closing, stated that the excess of peritoneal fat could be removed during the operation, as he had done on two occasions.

DR. W. T. ECKLEY, Chicago, Ill., read a paper entitled,

EVOLUTION OF THE MAMMALIAN STRAIGHT GUT, WITH SPECIAL REFERENCE TO PERITONEAL CHANGES INCIDENT TO ROTATION,

in which he emphasized the importance of a thorough knowledge of the embryonic arrangement, as well as the position in adult life, of the liver, stomach, spleen, pancreas, intestines and other abdominal organs, and he felt that the best way of teaching this subject was by various mechanical devices showing the different developmental stages and also by the study of the lower animals.

DR. WILLIS of California, in discussing this paper, urged upon the members the necessity for the more thorough training of the medical student in anatomy.

THE VALUE OF ENTEROSTOMY IN SELECTED CASES OF PERITONITIS,

was the title of a paper read by DR. FRED. B. LUND, Boston, in which he referred to the very grave condition of diffuse peritonitis with intestinal paralysis complicating appendicitis, respiration perhaps being interfered with by mechanical obstruction, and the patient being in all probability too weak to stand a radical operation. In these cases he emphasized the value of enterostomy as a primary operation, and reported several cases in which it had been performed with good results. The fistula he closed by secondary operation under local anesthesia.

DR. M. B. TINKER, Baltimore, Md., stated that enterostomy had been used in selected cases in the Johns Hopkins Hospital for several years,

the chief objection to it being the fecal fistula, which it is difficult to keep clean, and the liability of excoriation of the skin. Enterostomy he believed to be preferable to colostomy, and in many cases, if properly done, secondary operation is not required. It is of great value in certain cases of intestinal perforation, either appendiceal or typhoidal, where the patient is in too weak a condition to stand extensive surgical procedures.

DR. JOHN B. THOMAS, Washington, D. C., felt that very little good would result from doing the enterostomy unless the cause of the peritonitis was relieved. He recommended that the radical operation be done first, and then, if necessary, an enterostomy.

DR. JAMES B. BULLIT, Louisville, Ky., recommended that enterostomy be used where the patient after the operation developed well-marked tympany, and also for the temporary relief of peritonitis prior to the operation.

DR. F. A. DUNSMOOR, Minneapolis, Minn., recommended the performance of enterostomy when indications seemed to demand it either prior or subsequent to operation, and in cases of perforation he felt that the intestines should be handled as little as possible, and that this operation, in conjunction with the washing out of the abdominal cavity with saline solution, would produce the best results.

DR. LUND, in closing, stated that he would rather close the fistulas than wait for nature to do the work, and that he believed most patients preferred this mode of procedure. He did not believe that the abdominal cavity should be washed out at the time of the primary operation, and if the patient was of easy access he would do nothing more than the enterostomy at that time.

DR. F. D. SMYTHE, Memphis, Tenn., read a paper entitled

CHOLECYSTECTOMY *vs.* CHOLECYSTORRHAPHY AND CHOLECYSTOSTOMY,

in which he stated that the life of the patient demands removal of the gall bladder in malignancy and gangrene, and while not absolutely necessary as a life-saving measure, it is the better procedure to remove it if the cystic duct is obliterated, or if it presents macroscopic evidences of disease, infection, thickening, etc.

THIRD DAY — MORNING SESSION.

SUNSHINE AND FRESH AIR *vs.* THE FINSEN ULTRA-VIOLET RAYS AND THE ROENTGEN RAY IN TUBERCULOSIS OF THE JOINTS AND BONES,

was the title of a paper read by DR. DEFOREST WILLARD, Philadelphia, which he summarized as follows:

(1) Sunlight, fresh air and good food, together with fixation of the joint, are the most important agents in the contest with tubercular infection of the hard tissues.

(2) Direct exposure to the rays of the sun is essential, and all hospitals should be provided with solaria or sun porches and roof gardens.

(3) Patients lying in bed should have the diseased joints exposed to the direct rays of the sun, their heads and eyes being protected by green glasses or shades. The joints may be covered with blue so as to secure easiest passage of the ultra-violet actinic rays, and local medications rich in iodine may be employed as desired.

(4) Tent life on the hospital grounds, or better, in the open pine forest, can be successfully employed through both summer and winter.

(5) Sanatoria should be instituted for tuberculosis of the hard tissues as well as of the soft.

(6) The concentration of the sun's rays by lenses, as suggested by Butler, Finsen and others, is of positive benefit in bactericidal power. As final curative agents, however, the direct sun's rays are more effective. The electric rays are valuable in the absence of sunshine.

(7) The Roentgen rays in the laboratory have an inhibitory power upon the tubercle bacillus, and may prove useful in restraining the growth of these micro-organisms in living tissues.

(8) The actinic rays and the x-rays are both apparently helpful in the fight with tuberculosis, but several years will be required to determine accurately their effect. They should be employed not to supersede but to antedate and to supplement operative procedures, and to assist the mechanical and general therapeutic measures employed.

DR. J. CLARK STEWART, Minneapolis, Minn., read a paper entitled

EPITHELIOMA UNDER THE X-RAY; A PRELIMINARY REPORT OF THE HISTOLOGICAL CHANGES,

in which he drew a careful comparison of the degenerative changes as reported by Ellis and the case which he had studied, which was the case of an epithelioma on the back of the hand of a Norwegian woman fifty-two years of age. Seven sections were removed at varying intervals during the treatment and showed the following degenerative changes: (1) Fatty degeneration; (2) vascular changes; (3) elastic tissue and granular cells; and (4) hyaline degeneration. He believed that the effect of the x-ray upon these conditions was due to a fatty degeneration rather than the degeneration of polynuclear leucocytes described by Ellis.

(To be continued.)

VICTIMS OF THE ALPS. — The "playground of Europe," as the Alpine region has been called, is annually the graveyard of many adventuresome tourists. This year the death roll has been even above the average, for already there have been recorded more than three hundred accidents, resulting in the death of one hundred and fifty visitors. The causes of this unprecedentedly large number of accidents, have been two — cold and stormy weather and the foolhardiness of attempting dangerous ascents without guides. — *Medical Record.*

THE BOSTON

Medical and Surgical Journal

THURSDAY, AUGUST 27, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

27 AND 29 BROMFIELD STREET, BOSTON, MASS.

HYDROPHOBIA.

THE disease hydrophobia, though fortunately of rare occurrence, is so fatal in its outcome and so intimately associated in its genesis with matters of increasing pathological import that our interest in it is, and should be, continually revived. In the issue of the *Medical News* for Aug. 15, 1903, a large part of the number is taken up with articles from various writers on the general subject of hydrophobia, its literature, pathology, prophylaxis and prevention.

Dr. F. L. Taylor writes an interesting paper in which he discusses several of these points, drawing attention to the fact that the disease was originally described by Aristotle, by several men in the eighteenth century and in the beginning of the nineteenth century. In 1871 Galtier produced the disease in rabbits, and in 1880 Nocard and Paul Bert began laboratory investigations on the subject. Pasteur's revolutionary work, which is still bearing rich fruit, is universally known, and it is now generally recognized that the virus of the disease is found in the nervous system, salivary glands, the pancreas and in various other parts of the body. It is not found in the blood. Much work has of late been done upon the pathological anatomy of the conditions with apparently perfectly positive results regarding the nervous system. The names of Nélis and Babés in Paris and McCarthy and Ravenel in this country are well known in this connection. The alterations in nerve cells, particularly of the posterior dorsal root ganglia and other collections of cells, are now generally recognized as practically pathognomonic. Such changes, which have been described as the rabic tubercle, are pictured in this JOURNAL in our issue of Feb. 6, 1902. The demonstration of these alterations, which has now been repeatedly made, is clearly of very great advantage in determining immediately the existence of hydrophobia, and naturally may be accomplished in a much briefer period than is necessary in inoculation experiments.

Dr. Taylor discusses prophylactic inoculations, and reaches the generally accepted conclusion that in spite of a few mishaps the very great value of this method of treatment is beyond question. Regarding serumtherapy he also thinks that there is much future promise that new light may soon be thrown upon this subject. A very considerable work has already been done, but the method up to this time has not been applied to the human subject. More work remains to be done before the method can be regarded as particularly useful, although its scientific possibilities are already evident.

Dr. W. B. Pritchard also contributes a short paper, which concerns itself chiefly with the symptoms and diagnosis of the disease. Dr. H. D. Gill, a veterinary surgeon of New York, in his paper, which was read before the Alumni Association of the Bellevue Medical College, after discussing the general subject, makes the following statements of the precautions to be observed to secure absolute public safety:

(1) To place the city dog handling under proper medical or veterinary jurisdiction; (2) to prohibit all dogs from running at large unless muzzled or, at least, muzzle all dogs in infected areas; (3) to provide separate compartments in the wagon and at the pound for each dog; (4) to provide safe and proper places for the keeping of dogs suspected of having rabies, especially if they have bitten other dogs or a person; (5) every dog bitten by a rabid animal should be destroyed or quarantined for at least one year.

Methods of preventing hydrophobia are discussed by Dr. Follen Cabot, in which he urges, after experimental study, that treatment of the wound is of very great value. He recognizes nitric acid and actual cautery, but has slight respect for nitrate of silver. Mere cleansing of the wound and scrubbing with soap and water he found had some effect. Dr. Cabot makes a strong plea to the profession to make a more thorough study of the subject and not to fail to act promptly in the preliminary treatment of the injury.

It would seem that hydrophobia might quickly be placed in the category of the absolutely preventable diseases, but in one sense this is far more difficult of accomplishment than in diseases like smallpox or diphtheria, which do not occur among the lower animals. So long as animals are kept

as pets, or for domestic or other uses, it is inevitable that a certain amount of hydrophobia will continue to exist. For this reason it is highly desirable that every precaution should be taken that instructions to the owners of such animals should be general and that when hydrophobia is actually discovered, the treatment should be radical and complete.

THE BRITISH MEDICAL ASSOCIATION.

ONE of the most important and far-reaching meetings among medical men is the annual meeting of the British Medical Association. This association gathers together a very large number of physicians each year, is apparently democratic in its organization and usually, in the various addresses which are delivered, voices the spirit of progress in medical matters throughout the world. This year the seventy-first annual meeting of the association was held at Swansea. Commenting on the meeting, the *Lancet* states that the attendance was not so large as usual, which it attributes in part to the remoteness of the place of meeting from any well-known university center. The cause of this year's visit to Swansea was the fact that it met there in 1853 and this year, therefore, commemorates the fiftieth anniversary.

Apparently the effect which Swansea produced upon the visiting members was not altogether enlivening, due in a measure to the unpropitious weather. The following is the description which the *Lancet* gives of the event:

> First impressions of Swansea were not lively, but the courtesy and kindness of every one brightened those impressions. Those members of the Association who arrived at Swansea on July 27 approached the town through a thick, murky canopy of smoke rendered especially disagreeable by heavy rain. Despite the elements, however, the streets were encumbered with a multitude assembled to do honor to their countryman, the Welsh volunteer who had gained the King's Prize at Bisley and was returning to Swansea on that day. Visitors to Swansea had been warned not to expect anything beautiful in the place, and the narrow, monotonous streets, in which no trace of architectural ambition appears, looked their worst in the downpour.

It is an unfortunate fact, but none the less true, that the complete success of these yearly medical gatherings is dependent upon various purely external conditions. Pleasant weather and cheerful surroundings are quite enough to lead to the success of such gatherings, despite the fact that medical communications may not be of an exhilarating character. We have always maintained, therefore, and we think with justice, that it is desirable in selecting a place of meeting that various matters purely external to the supposed main issue should be considered. The *Lancet*, in spite of an attempt at enthusiasm, apparently does not regard this meeting of the British Medical Association as an absolutely complete success. This we suspect was due to the external conditions of which we have spoken and also to the somewhat unoriginal character of certain of the addresses, which were not altogether up to the high standard set in previous years by this association.

The address in medicine was delivered by Dr. Frederick T. Roberts, on the subject of "Infective and Infectious Diseases." In one of the opening paragraphs of this address he says:

> It has always seemed to me desirable that the "Address in Medicine" at the annual meeting of the British Medical Association should be devoted to some particular subject of more or less general interest and not savoring, so far as can be possibly avoided, of the absurd, irrational and most mischievous "specialism" which is so rampant at the present day.

Inasmuch as many members of his audience must have been specialists, it is probable that this somewhat uncalled-for attack was received with coolness. It is always hard to say why specialism, which has arisen through a perfectly natural process of development, should be so viciously attacked by men in high standing in the profession. Such attacks, coming from such sources, can, however, have no other ultimate result than to bridge the gulf which certain men seem to delight in increasing. Certain things it is well to accept and make the best of, and one of these is specialism. This address in general is taken up with a detailed discussion of what has hitherto been accomplished in relation to infectious diseases and adds little new to the knowledge which we already have.

Dr. T. D. Griffiths delivered the president's address, on the somewhat threadbare subject of the "Evolution of Antiseptic Surgery." Here again the history, always edifying, of the development of modern surgical practice was detailed at great length.

A. W. Mayo Robeson, F.R.C.S., gave the address in surgery, consisting essentially of personal reminiscences and the experience gained from the performance of two thousand operations on the abdomen.

At the annual dinner, held also at Swansea, there was a large amount of after-dinner speaking. The toast of "Our Guests and Friends from Over the Sea" was responded to very briefly by Professor Senator of Berlin and Professor Adami

of Montreal. We note no name from the United States.

THE PATHOLOGY OF SMALLPOX.

IN the last number of the *Johns Hopkins Hospital Bulletin* Dr. William Royal Stokes offers an article on the pathology of smallpox based on a careful pathological study of five autopsies and sections and cultures from six non-fatal cases. Dr. Stokes discusses in very considerable detail, yet in concise fashion, the various lesions found in the internal organs and the microscopical appearances in patients dying of smallpox. As a succinct statement of these alterations, the article is of very considerable value, particularly since it is accompanied by a large series of half-tone plates. As already determined by other investigators, Stokes concludes that streptococcus infection is the most striking feature of fatal smallpox and that the course of this infection may be traced from the skin to the general circulation. In four of his fatal cases he found streptococci in the pustules and in the heart, liver, kidney, spleen, lymph glands, pancreas and lung.

We should have expected in any paper on smallpox, written at this time, a discussion, or at least a detailed mention, of Councilman's, Magrath's and Brinckerhoff's recent striking work on the subject. This we miss and, although the paper must be regarded as a certain addition to our general knowledge, it is hardly to be considered as a wholly modern view of the smallpox question, owing to the omission of the recent protozoa theories.

MEDICAL NOTES.

FRENCH CONGRESSES ON ALCOHOL AND TUBERCULOSIS. — It is announced that the First National Anti-Alcohol Congress is to be held from Oct. 26 to 29 in Paris. The attempt will be made to outline the present state of affairs regarding alcoholism and, in the second place, to plan out a comprehensive method of combating the evil. The French Congress to combat tuberculosis also meets on the same dates at the amphitheatre of the Faculty of Medicine in Paris.

RETIREMENT OF PROF. KARL SCHÖNBORN. — It is announced that Dr Karl Schönborn is to resign his professorship at the University of Würzburg because of illness. His life has been a peculiarly active one, particularly at the time of the Franco-Prussian War, when he had charge of various clinics at Berlin, Langenbeck and Bardeleben, having left for the seat of war.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Aug. 26, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 35, scarlatina 17, typhoid fever 25, measles 14, smallpox 0.

THE ADULT BLIND. — At a recent meeting of the Executive Council, Governor Bates of Massachusetts made nominations for a new commission on the adult blind as follows: Dr. Edward M. Hartwell of Jamaica Plain, Miss Agnes Irwin of Cambridge and Alpheus H. Hardy, Esq., of Boston. This commission is appointed under a resolve of the last Legislature for the purpose of investigating the condition of the adult blind. The resolve provided that the commission should serve without compensation, but might employ such assistants as required and also be provided with funds necessary for traveling, etc. Its object is to investigate the condition of the adult blind within this Commonwealth, to consider means of amelioration and the possible expediency of an industrial training school or other institution, a report to be made to the General Court on or before Jan. 15, 1904.

NEW YORK.

ARREST OF BABY INCUBATOR EXHIBITOR. — A baby incubator exhibit having been established at Coney Island, the Society for the Prevention of Cruelty to Children recently caused the arrest of one of the proprietors on the charge of conducting a "baby farm." The case was brought to the Coney Island Court, and Dr. Martin A. Cooney, the inventor of the incubator, being called upon to testify, stated that in Buffalo the lives of fifty out of fifty-two infants had been saved by its means and that out of nineteen cared for thus far at Coney Island, but one had been lost. In order to enable the court to come to an intelligent decision in the matter, a committee, consisting of Dr. William Brennan, of the State Medical Board, the Superintendent of the State Charities Department and the President of the New York Board of Health, was appointed to investigate and express an expert opinion. As a result, the committee were so favorably impressed with the merits of the apparatus that they recommended that at the close of the exhibition at Coney Island the incubators should be purchased by the city, half of them to be sent to Bellevue Hospital and the others to the Kings County Hospital in Brooklyn.

PLANS FOR THE NEW WOMAN'S HOSPITAL. — The plans for the new Woman's Hospital to be erected in West 110th Street have just been filed with the Building Department. The hospital will be six stories in height, with basement and attic, and will have façades of granite, limestone and terra cotta. The main building will be 188 feet in length and 40 feet deep and there will be two wings, each 60 feet long and 40 feet deep. In the basement will be a pathological museum and a clinic for out-patients and the first floor will contain, besides the administration offices, a lecture hall and a chapel with a seating capacity of one hundred and fifty. The cost is estimated at $610,000. The Woman's Hospital was founded by Marion Sims and its surgeons have always maintained it in the first rank of such institutions.

THE STONY WOLD SANITARIUM. — The Stony Wold Sanitarium at Lake Kushaqua, fifteen miles from Paul Smith's in the Adirondacks, was formally opened on Aug. 15 with addresses by Bishop Potter and Dr. E. L. Trudeau of Saranac Lake. Among the large assemblage present were a number of New York physicians who are especially interested in the subject of tuberculosis: Drs. James E. Newcomb, whose wife is president of the institution; H. M. Briggs; Alfred Meyer; Charles H. Knight; Charles M. Cauldwell and S. Knopf. The money for the establishment of Stony Wold, the movement for which was inaugurated as long ago as 1891, has been raised through the efforts of the ladies of New York. The institution is intended for women and young girls suffering from incipient tuberculosis. The expenditure thus far has amounted to more than $150,000, and some $30,000 is still needed to bring it to completion. One of the most attractive of the buildings is the Memorial Dormitory, costing $38,000, of which $20,000 was given by Henry Sigel. Probably the largest single donation to the sanitarium was one of $25,000 by John D. Rockefeller.

LAWS FOR THE PROTECTION OF CHILDREN. — Several laws enacted at the last session of the Legislature for the better protection of children will go into effect on Sept. 1. One of these will meet a condition which has given rise to much complaint. In the past, children under sixteen were frequently held in station houses and places of detention over night and sometimes longer, to the prejudice of their health and morals. This new law provides that whenever a child under sixteen is arrested in any city of the first class for the violation of a corporation ordinance or other minor offence, or for peddling newspapers without a license under the recent newsboys' license act, the police captain or sergeant before whom the child is brought may accept in lieu of bail the personal recognizance, in writing, without security, of a parent, guardian or lawful custodian of such child, to produce the child before the proper magistrate at the time required. By another act the general establishment of children's courts, which have proved beneficent in the larger cities, is made obligatory, the new law requiring that all cases involving the commitment or trial of children actually or apparently under the age of sixteen shall be heard and determined apart from a trial of other criminal cases. A separate docket and record shall be kept and, so far as practicable, a separate room used, to be known as the "children's court."

Miscellany.

CHOLERA IN THE PHILIPPINES.

CHOLERA showed an increase a few weeks ago in the number of cases reported from the provinces to the Manila Board of Health and nearly all the large islands still have foci of infection. Several sharp little outbreaks have occurred, particularly in the southern islands. Thus at Panay, on the island of Panay, 47 cases with 29 deaths were reported as occurring in one day lately. The infection on this island has been very persistent and Panay shows a much higher mortality than any other island in proportion to its population. Cholera exists in the most northern and most southern provinces of Luzon, and a considerable number of cases are occurring in a few badly infected villages. In the provinces near Manila, sporadic cases crop up every now and then. Cholera has occurred on a number of boats returning to Manila from provincial ports, but these have been held up and the vessels sent to the Mariveles quarantine. Manila has been free from cholera for more than two months, but twelve cases having occurred since the beginning of the year. Four cases developed lately on the waterfront, however, in which the disease could not be traced to any outside source, and there is no reason why Manila, like some of the provincial cities, should not have a few foci of infection still existing and ready to light up another outbreak with the onset of the rains. There is also a strong probability that foodstuffs brought in from the surrounding country are occasionally infected and this matter of infection of a food supply is much more difficult to handle here than it would be in the United States. There is no way of confining the population to the use of foods which are known not to be infected, as nearly all the articles of food eaten by the Fili-

pino are used fresh, there are practically no facilities for cold storage and tinned articles of food are too costly to ever become even an important article of diet with the native. "Living from the can" was a resource for the foreigners here which undoubtedly saved many lives in the past year; but it was financially beyond the power of the poorer natives to take advantage of this means of protection. Much rice, fruit, eggs, vegetables, etc., are imported from the Asian mainland, but the ports of departure have been infected and the delay due to necessary quarantine caused all perishable articles to spoil. It was by such imported foods that the original infection gained entrance to the islands. Under the circumstances, and appreciating that the poorer Filipino in Manila does not keep a day's supply of food ahead, it is necessary in practice to modify rules which, in theory, should be strictly applied. The only thing to do is to interdict the sale of certain of the more dangerous foodstuffs and try and educate the natives into using only foods which are fresh and have been thoroughly cooked. This apparently simple task is really most difficult, for it goes against the local customs which have come down from time immemorial; while the native objects to any interference with his habits and customs, and present political conditions require that he shall be handled with tact and diplomacy. Up to date the official reports on the cholera epidemic received by the health authorities show a total of 131,846 cases and 83,300 deaths for the archipelago, giving a mortality of 63%. The first two figures are undoubtedly much too low, as many cases have never been reported; the mortality rate is somewhat too high, as it is based chiefly on the more severe cases, which are most liable to come under official notice. Probably the total number of cases so far should be placed at about 250,000 and the deaths in the neighborhood of 150,000, giving a mortality of about 60%. So far, there have been 4,681 reported cases, with 3,472 deaths, in the city of Manila. In the island of Luzon, the town of Aparri, on the north coast, is reported as being badly infected, with 19 cases and 15 deaths reported for one day alone. The municipal authorities have been denying the presence of the disease and the condition has finally been determined by special inspector sent from Manila. In the meantime no steps were taken to prevent the disease, and the latter has taken advantage of the opportunity to spread to several neighboring villages. The military authorities in the vicinity had early recognized the presence of the disease and promptly took steps which have prevented the troops from becoming infected. As soon as the presence of cholera in Aparri was officially stated, a number of towns quarantined against that city and vigorous repressive measures were instituted. Unfortunately, a number of the natives, learning of the presence of the inspector and appreciating that cholera did exist, promptly scattered among the provincial towns to avoid the quarantine which they felt sure would be instituted.

Correspondence.

ADVANTAGES OF SMALL DOSES OF OPIUM.

BOSTON, Aug. 20, 1903.

MR. EDITOR: The object of this communication is to assert the benefits to be derived from moderate and even small doses of opium, in certain cases. To quiet pain and to procure sleep mean also to rest the nervous system and to strengthen the whole body. It is well known that small doses of opium are stimulating and large doses narcotic. I believe that moderate doses possess both these properties.

Chronic disease is usually organic. Organic disease is incurable. But peace and life may be conserved by moderate doses of opium — I mean by not exceeding one grain of opium in twenty-four hours and often by half a grain of opium. This may be considered equivalent to one sixth of a grain of morphia or to one twelfth of a grain of morphia respectively. But the effects of opium and morphia are different. Crude opium (the gum) in suppository, by the rectum, is one of the best forms. When given by the mouth, a preparation called Liquor Opii Compositus, made by Squibb, has been used by me a long while, with unvarying effect. Seventeen drops of this fluid contain one grain of opium. By suppository, one half a grain of crude opium is often sufficient.

Finding a case of cancer of the rectum, high up, in a middle aged female, I began with one half a grain of opium in the rectum daily. This was enough for several months; the patient lived about fourteen months and the amount of opium was very slowly increased, but was never large. Now if one had begun with the common remedy of one quarter of a grain of morphia and a little extract of belladonna, as is often done, the increase to one third, one half, one whole grain of morphia would have followed and with some bad results. Begin low down, as little as will palliate. Increase with reluctance; one half a grain of opium by rectum, each twenty-four hours, has now been in use six years, by a patient with colitis, mal-assimilation and two to four painful stools each morning.

Five drops of Squibb's Liquor Opii Compositus, in a delicate female, will sometimes suffice to quiet moderate neuralgia and procure a nap; ten drops is a tolerably narcotic dose and lasts all night; fifteen drops will be needed for colic, if severe. Meanwhile the use of the solid extract of valerian will help nervous wakefulness and the restlessness of afternoon hectic, and when this fails, bromide of sodium will suffice, but its after-effects are depressing. Opium is not depressing, and when used habitually, in moderate doses, is not constipating.

Assafetida is a very valuable adjunct; it is quieting, supporting and stimulating. Now we shall surely find that the piling up of doses of morphia is disappointing. Especially in promoting euthanasy, morphia in moderate dose does all it can do; in larger and larger doses it absolutely fails. In such distressing and fatal conditions, chloral may be tried with success, but chloroform, by inhalation, should be allowed, provided the friends understand and wish it and the patient longs for unconsciousness. Bear in mind, when the breathing is shallow, that death from chloroform may follow.

Truly yours,
DAVID W. CHEEVER.

APPENDICITIS IN A PATIENT WITH TRANSPOSED ORGANS.

211 STATE STREET, PORTLAND ME.,
Aug. 21, 1903.

MR. EDITOR: Maggie L. came into my service June 11, 1903.

Examination showed general septic peritonitis, probably appendiceal in origin. The apex beat was found in the right chest one inch to the right of and on a level with the right nipple. Incisions in the abdominal wall showed a complete transposition of all the abdominal organs. The appendix, surrounded by a large abscess, was found on the left side, the rectum being in the normal position of the appendix. Postmortem examination confirmed the previous findings. I was unable to obtain permission for a complete autopsy.

Truly yours,
JOHN F. THOMPSON, M.D.

RECORD OF MORTALITY

Deaths reported, 3,234; under five years of age, 1,288; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,115, acute lung diseases 189, consumption 338, scarlet fever 16, whooping cough 36, cerebrospinal meningitis 10, smallpox 19, erysipelas 6, measles 12, typhoid fever 55, diarrheal diseases 606, diphtheria and croup 49.

From whooping cough, New York 8, Chicago 9, Philadelphia 8, Baltimore 3, Pittsburg 4, and Cambridge, Fitchburg, North Adams and Woburn 1 each. From erysipelas, Philadelphia 1, Pittsburg 2, Boston 3. From smallpox, Philadelphia 7, Pittsburg 12. From scarlet fever, New York 2, Chicago 2, Philadelphia 6, Baltimore 1, Pittsburg 3, New Bedford 1, North Adams, 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Aug. 1, the death-rate was 14.4. Deaths reported, 4,158; acute diseases of the respiratory organs (London) 110, whooping cough 49, diphtheria 51, measles 84, smallpox 5, scarlet fever 43.

The death-rate ranged from 3.3 in Hornsey to 25.9 in Warrington; London 13.5, West Ham 11.7, Brighton 15.0, Portsmouth 15.5, Southampton 16.6, Plymouth 6.5, Bristol 10.9, Birmingham 12.5, Leicester 13.3, Nottingham 15.9, Bolton 17.1, Manchester 17.7, Salford 15.2, Bradford 15.5, Leeds 16.6, Hull 16.3, Newcastle-on-Tyne 18.3, Cardiff 11.5, Rhondda 17.4, Liverpool 21.2, Tottenham 7.6, Great Yarmouth 20.1.

METEOROLOGICAL RECORD.

For the week ending Aug. 15, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING AUG. 22, 1903.

A. G. GRUNWELL and W. H. BUCHER, surgeons. Appointed surgeons from June 20, 1903.

J. C. THOMPSON, passed assistant surgeon. Commissioned as such Aug. 10, 1903.

F. W. F. WIEBER, surgeon. Ordered to the "Prairie" Aug. 21.

R. E. RIGGS, assistant surgeon. Detached from the Naval Hospital, Philadelphia, and ordered to the Navy Yard, Washington, D. C.

H. L. BROWN, assistant surgeon. Detached from the Navy Yard, Washington, D. C., and ordered to the Naval Hospital, Philadelphia, Pa.

H. G. BEYER, surgeon. Detached from the "Prairie" and ordered to duty as member of a Board on Barracks.

A. D. MCLEAN, assistant surgeon. Ordered to the "Wabash," Boston, Mass.

S. L. SCOTT, assistant surgeon. Ordered to the Naval Hospital, Chelsea, Mass.

J. A. RANDALL, assistant surgeon. Ordered to the Naval Hospital, Norfolk, Va.

F. G. ABEKEN, assistant surgeon. Ordered to the Naval Hospital, New York.

APPOINTMENTS.

DR. CHARLES H. HOLMES of New York has been appointed junior physician at the Manhattan State Hospital for the Insane on Blackwell's Island.

The following changes have taken place in the Faculty of the Tufts College Medical School: E. M. Plummer, M.D., has been elected Professor of Otology in the place of F. L. Jack, resigned; James S. Howe, M.D., Professor of Dermatology; George W. Kaan, M.D., Professor of Clinical Gynecology; John L. Ames, M.D., assistant Professor of Clinical Medicine; Gardner W. Allen, M.D., assistant Professor of Genito-Urinary Surgery; and Charles F. Painter, M.D., assistant Professor of Orthopedic Surgery.

SOCIETY NOTICES.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION. — The thirteenth annual convention will be held at the Hotel Windsor, Atlantic City, N. J., on Sept. 22, 23 and 24, 1903.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS. — The American Association of Obstetricians and Gynecologists will hold its sixteenth annual meeting in the Northwestern University Medical School Building, Chicago, Ill., Sept. 22, 23 and 24, 1903, under the presidency of Dr. Lehman H. Dunning of Indianapolis.

MEDICAL SOCIETY OF THE MISSOURI VALLEY. — The annual meeting of this society will be held in Omaha, Sept. 14, 15, instead of 17, as previously announced.

RECENT DEATH.

Mr. Herman D. Osgood, who is said to have been the first to use nitrous oxide gas in dental operations, died Aug. 22, at Concord, Mass.

Original Articles.

THE RESISTANCE OF TISSUES AS A FACTOR IN THE MANUAL REDUCTION OF CONGENITAL HIP DISLOCATION.

BY E. H. BRADFORD, M.D., BOSTON.

It is now universally admitted that the chief obstacle in the reduction of a congenitally dislocated hip lies in the soft parts rather than the bone, and it is manifestly of practical interest to determine which tissues offer the greatest resistance.

It has been a matter of discussion whether the greatest difficulty is encountered in overcoming the altered capsule or from certain shortened muscles. Reasoning from analogy, from normal anatomy and the strength of the capsule and ligaments of the hip, many writers, myself among them, have believed that these rather than the muscles were of the greatest importance in maintaining the dislocated position in a congenitally dislocated hip, as the capsule and ligaments offer the chief obstacle to a dislocation in a normal hip.

The writer has been led to give up the opinion that in the capsular resistance the chief obstacle to reduction is to be found, by his recent experience in operating by incision in certain resistant cases, from which it has been clear that even after all capsular contraction has been removed and the capsule entirely freed from any connection with the neck of the femur, the lesser trochanter or the shaft within a half an inch below the lesser trochanter, a formidable obstacle often remains to elongating the limb to its normal length or to placing the head of the femur sufficiently below the acetabulum. If this obstacle does not lie in the capsule it must be found in the muscles; and if in the muscles, it appears to be beyond the limit of skill by manual manipulative reduction where failure or disaster have followed manual reduction. Following this line of reasoning, the question presents itself as to the practicability of using a more thorough division of the muscles as an aid to reduction than has hitherto been employed.

Tenotomy and myotomy have been tried in the reduction of congenital dislocation of the hip by a few surgeons, but the method has not received general acceptance, perhaps because the attention of the surgical world has been turned to other methods, and perhaps also to a degree because the precise usefulness of the method has not been carefully studied. Tenotomy alone will not cure clubfoot. It is only within a century that its general use was advocated. At one time, however, tenotomy was regarded as the only important factor in the correction of clubfoot by surgeons, and relapse was the usual result. It is certainly true that myotomy and tenotomy of the muscles around the hip in congenital dislocation are of no benefit unless used in connection with careful manipulation. Now, however, that the manipulative method has been carefully studied and is of approved efficiency, may we not also take advantage of tenotomy as an aid? The objections which have been urged against the use of the knife in congenital correction of deformity are the danger of sepsis, that extensive excision would be needed which would lead to cicatrization and also that it is an unnecessary procedure. Are these objections valid? The subject is one in which anatomical investigation can be made with advantage.

Through the courtesy of Professor Dwight, the anatomical opportunities of the Harvard Medical School were placed at my disposal, and an adult dissecting room cadaver was examined by Professor Dwight and myself to discover the possibility, with moderate force, of lengthening the limb by traction. It was found that where the capsule of the hip joint was freely incised a slight amount of lengthening of the limb could be gained by traction. When the long adductor and hamstring muscles were divided and the fascia lata cut, the limb could easily be lengthened two inches more.

The largest group of the muscles to be considered is the adductors. The glutei have been shown by Hoffa and Lorenz not to be a factor in the problem of congenital dislocation of the hip. The quadriceps extensor, with the exception of the reflected head of the rectus, is a femoral muscle and the reflected head and the psoas iliacus are useful in flexion of the thigh and are of but little importance in the problem to be considered. The adductor and hamstring group are manifestly the most important in their resistance to an abducting and a traction force.

If the muscles of the adductor group are examined it will be found that the structure of the several muscles differs with their situation and probably with their function. The adductor longus, which is the most prominent superficially, is a long-fibered muscle, a companion to the gracilis, and stretched without the exercise of great force. Its attachment to the symphysis is superficial and easily divided by a knife. This muscle presents but relatively slight obstacle to forcible correction either in abduction or downward traction. The adductor brevis, a shorter and thicker muscle, is, as is the medius, attached to the upper part of the femur and serves partly like the quadratus lumborum, the pyramidalis and gemelli, to hold the head of the femur well into the acetabulum. These muscles are not firmly fibered and with comparatively few intramuscular septa. They are beyond the reach of the knife in any practical surgical procedure short of amputation. Their resistance would be to extreme abduction and but little to a downward pull.

The adductor magnus, the largest and strongest muscle of the group, has a double function at its upper attachment to the femur. It acts purely as an abductor and its fan-like insertion along the middle of the femur to the junction of the middle and lower third makes it, with its fan-like intra-muscular septa, its toughness, its broad and strong origin, the most powerful of the whole group. The greater part of the muscle is of fleshy fiber, but the long inner edges and the

lower fibers are grouped into a strong tendon, which passes over and to the inside of Hunter's canal, and is inserted into the tubercle of the adductor magnus above the internal condyle. If this tendon is examined it will be seen that it is one of the strongest tendons of the body. From its position and strength it is clear that it offers the strongest resistance both to downward pull and to abducting force. If this is overcome comparatively little resistance will be offered by the other muscles, and unless this is overcome but little will be gained in resistant cases either in elongating the limb or in increasing the arc of its abduction. It would appear, therefore, that if the long tendon of the adductor magnus were divided at its insertion at the lower end of the femur (a simple and harmless procedure) one important obstacle to diminishing the resistance in correction could be removed. After this correction, force in resistant cases in the direction of abduction is much easier and resistance to a downward pull much diminished.

The hamstring group presents a formidable resistance to a downward pull. The muscles are strong, with long tendinous insertion. They can be relaxed, however, in manipulative correction by flexing the leg, and can be easily divided by tenotomy. The long insertion of the tensor vaginæ femoris or the ilio-tibial ligament presents a formidable obstacle to downward traction. If, however, the limb is abducted, the resistance of the tissue to the success of manipulative correction is slight. The ligament is superficial and can be as easily divided by a tenotome as the planta fascia.

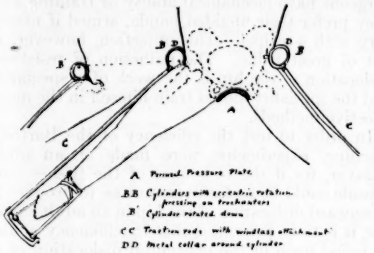
It would appear, therefore, that the chief muscular obstacle in manipulative reduction lies in the long tendon of the adductor and in the hamstring tendons. It of course does not follow that division of these muscles is necessary or advisable in all cases or if done will make the manipulative correction easy, but it follows that this procedure, not a difficult one, will, in the resistant cases, diminish the resistance with no increase in the danger.

The following observations were made at the dissecting room of the Harvard Medical School by Dr. L. T. Wilson, and illustrate the effect of division of the adductor magnus and other tendons on the resistance of a limb to direct traction :

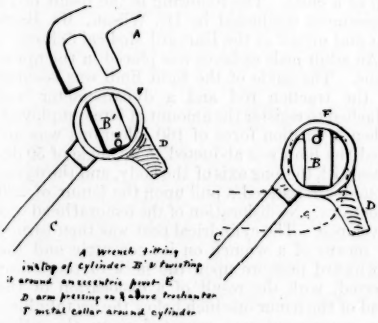
A full-term fetus, twenty inches long and weighing nine and three-quarters pounds, was placed on its back and its pelvis fastened immovably to the table. A traction dynamometer was fastened to the right ankle. A pin was driven into the right anterior spine and another into the right exterior tuberosity of the femur. Slight traction was made to straighten the leg and the distance between the pins measured (*A*). A traction of 30 kilograms was made and the distance measured showing an increase over *A* of one-eighth of an inch. The capsule of the hip-joint was then divided and traction of 30 kilograms made, showing an increase over A of one-half an inch. Tenotomy of the adductor magnus tendon, with an increase over *A* of one inch. The tensor vaginæ femoris was then cut, with an increase over A of one and one-eighth inches. The hamstrings were cut, with an increase over A of one and one-half inches. A traction of 30 kilograms was used each time. Traction was then made to see how far the femur could be drawn down, and at 40 kilograms the epiphyses at the knee gave way. Confirmatory tests on the other leg gave similar results.

An adult male cadaver was taken and the upper half of the body removed at the level of the iliac crests. The pelvis was then fastened immovably to the table and to a heavy post. A dynamometer was fastened around the right ankle and a tackle fastened to this and to a heavy post. A nail was driven into the anterior superior spine and another into the external tuberosity of the femur. Traction of 175 kilograms was made and the distance between the nails measured (*A*). The capsule was then cut (see later remarks) and traction of 175 kilograms made, showing an increase over A of one-half an inch. The tendon of the adductor magnus was tenotomized and traction made, with an increase over A of three-quarters of an inch. The hamstrings were cut and tension made, with an increase over A of three-quarters of an inch. The fascia lata was then cut and tension made, with an increase over A of seven-eighths of an inch.

These results being far from what was expected from Experiment I, investigation was made and



the capsule found not to be divided in many places, especially the back. This was fully cut and tension of 175 kilograms made and an increase over A found to be one and one-half inches.



A second hip was treated in the same manner with the following results: A traction of 150 kilograms was used. Measurement of A taken. Increase over A with the capsule thoroughly divided, one-half an inch. Increase over A with the capsule thoroughly divided and a tenotomy of the adductor magnus, three-quarters of an inch. Increase over A with the capsule cut and a tenotomy of the adductor magnus and tenotomy of the hamstring, three-quarters of an inch. Increase over A with the capsule divided and tenotomy of the adductor magnus, hamstrings and fascia lata, three-quarters of an inch. This case, however, was an old dissecting-room subject which had had the skin removed, and the muscles were fairly hard and dry.

Nothing could be more simple than the method of Lorenz in correcting the deformity in a young child, but in the more resistant cases the amount of force necessary brings the operator face to face with the danger either of using too great force and causing an unnecessary injury, or too little force and failing to effect reduction. Fractures of the femur may occur with injury to the soft tissues, due in part to the difficulty of regulating the amount of force used. There is difficulty on the part of the operator in securing the pelvis under his control, as both of his hands are occupied in the manipulation of the leg; the pelvis is left to an assistant. It is impossible that there should be complete harmony of muscular effort, and either too great or too little force may be used, — too great fracturing or bruising tissues unduly, or too little not overcoming the chief resistance, which appears to be the lower tendinous insertion of the adductor magnus. To stretch this muscle efficiently it is necessary that the pelvis be held securely; that there be traction force combined with an abducting force. If this force is arranged in such a way that the trochanter is pressed upon an immovable fulcrum and the limb is sufficiently pulled at the same time it is abducted there must be slight danger of fracture of the femur by crowding the head into the pelvis or resistant tissue. The resistance of the adductor magnus may be assumed to be less than the strength of the shaft of the bone. The adductor magnus protects from motion injurious to the soft tissues and these vessels and nerves cannot be injured until this tendon is stretched, torn or divided.

It is essential that the mechanical force employed should be directly under the control of the operator.

The necessary requirements are met with success in an apparatus devised by Mr. Bartlett of Boston, after careful investigation of the subject and observation of cases and pathological specimens at the Children's Hospital and Harvard Medical School. A full description of the device will be published later, but a less detailed account may be of interest. It consists of two metal cylindrical posts adjustable on a stand to press upon the pelvis above the trochanters. On these metal cylinders metal collars fit, to which a strong steel rod is secured with a windlass traction attachment. A rawhide strip hitched with a clove hitch to the padded ankle of the patient provides for traction to any desired extent, counter pressure being furnished by a metal perineal post. The traction rods are secured to the metal collar, which plays about the cylindrical post. Abduction and adduction, flexion and hyperextension combined with a pull are provided for.

The cylindrical post acts as a fulcrum to the abducting force of the rod, but as the center of this motion is outside of the position of the femoral head, abduction alone will act as a force which will bring the head of the femur from above the acetabulum to its level, if sufficient additional force is applied to stretch the hamstrings and adductors. To secure direct pressure upon the capsule and any contracted fibers which prevent the descent of the femoral head, a superimposed cylinder is placed upon the trochanter cylinder and on this a metal collar is fitted with a handle on one side and an arm on the other, fitted so as to press above the trochanter above and below the femoral neck. If this arm, while the limb is being stretched and abducted and the head pulled away from the ilium, can be forced down, the femoral neck and head will be pressed before it, provided the arm is fitted snugly around the neck and slipping is prevented. This is prevented by a cam motion of the superimposed cylinder, which is worked by a wrench. The surgeon holds the

handle which directs the pressure on the trochanter, and at the same time moves the wrench, forcing the cylinder to revolve, exerting a downward pressure of any required force and with adjustable accuracy. Under this force there is no danger of a fracture of the femoral neck or head, as they are free from resisting pressure. The tissues which will be torn are the shortest tissues alone, which can be torn without danger.

The objection to this appliance is the objection of every surgeon to all mechanical aids. Few surgeons have mechanical ability or training and they prefer their unaided hands, armed if necessary with a scalpel. This objection, however, is not of great value. The reduction of resistant dislocation of the hip is the work of a specialist and the specialist should train himself in the most effective methods.

In order to test the efficiency of the Bartlett machine, experiments were made on an adult cadaver, for if the resistance of the tissues and capsule could be so far overcome as to produce a downward dislocation of the hip in an adult cadaver, it is to be presumed that its efficiency could be relied upon in the congenital dislocation of a hip of a child. The following is the result of an experiment conducted by Dr. Wilson, Mr. Bartlett and myself at the Harvard Medical School:

An adult male cadaver was placed in the apparatus. The ankle of the right limb was secured to the traction rod and a dynamometer was attached to register the amount of force employed. When a traction force of 160 kilograms was applied the limb was abducted to an angle of 50 degrees with the long axis of the body, and the dynamometer registered a pull upon the femur of 220 kilograms. No dislocation of the femoral head was developed. The cylindrical post was then turned by means of a wrench on its eccentric and the downward pressure upon the neck of the femur exerted, with the result of a dislocation of the head of the femur one inch below the acetabulum. The experiment was repeated upon the other femur of the cadaver with a similar result. The amount of force required was not carefully registered by the dynamometer, as in applying the force to the upper eccentric the amount of abduction of the limb was lessened, thereby lowering the traction force and the force registered upon the dynamometer remained as before 220 kilograms.

From this it would appear that no mechanical obstacle exists to forcing the femoral head downward from its fixed position by the use of force within surgical limits. Experience with osteoclasis has demonstrated that a pressure of much over 250 kilograms is borne by tissues without injury. A traction force and an abducting force combined with a downward force upon the head of the strongly abducted femur appears to present an economy of effort.

As a complement to these experimental investigations, the principles here presented have been utilized practically at the Boston Children's Hospital in cases of congenital dislocation of the hip under treatment for the last four months.

The method of manipulative reduction with the aid of tenotomy of the adductor magnus tendon has been performed at the Children's Hospital in three cases. These cases were not of the most resistant type, but the aid given to the manipulation, making the correction much easier, was apparent.

Correction by the aid of mechanical force by the Bartlett machine without tenotomy has been done in a child of nine and in a child of six, fairly resistant cases, with success and much less effort than would be necessary by manual force. A combination of mechanical force and tenotomy was employed with great success in a child of thirteen, the reduction being made with great ease. This method has been tried in two younger children with success, but as the Lorenz method is simple and efficient in the younger cases, mechanical force is unnecessary.

The facts which are here presented for consideration may be summarized as follows:

(1) The resistance offered by the capsule to the correction of congenitally dislocated hips is not more important than that offered by the muscles.

(2) The chief resistance to forcible abduction is from the strong tendon of the adductor magnus.

(3) The resistance to pulling down the head comes from the hamstring group and the long tendon of the adductor magnus and ilio-tibial band.

(4) These resistant tissues can be overcome by small incisions at a distance from the hip.

(5) In the lighter cases manual manipulative reduction is sufficient.

(6) In resistant cases, mechanical force which pulls upon and abducts the limb, arranged so as to also directly act upon the capsule, is of assistance.

(7) Where the tendon of the adductor magnus is so strong that an immoderate amount of force is needed in stretching, it would seem advisable to divide the chief resisting tissues rather than to incur the danger of severely bruising the tissues by the force used. The division of the tendon can be done either before the operation of forcible correction or at the same time.

PRIVILEGED MEDICAL COMMUNICATIONS.

BY DAVID W. CHEEVER, M.D., BOSTON.

IN a court of justice a communication is called privileged if the witness may legally refuse to divulge it; or where he may be protected or sustained by the court, if he declines to answer. Such are the statements or revelations of a prisoner to his legal counsel. A privileged medical communication would be one made by a patient to his physician.

The Roman law protected the physician. And among Latin countries France made it a penal offence for the physician to disclose the confidence of his patient. But the English common law, so

lenient to the accused in most respects, assumes another position in regard to medical witnesses and obliges them to answer, or be held in contempt of court and subject to imprisonment.

"The highest legal authorities in England have decided that medical men enjoy no special privilege with regard to secrets of a professional nature. In other words, no practitioner can claim exemption from answering a question because the answer may or would involve a violation of secrecy, or even implicate the character of his patient."[1]

The law of Massachusetts follows the English law. To quote an authority: "Neither is protection extended to medical persons in regard to information they have acquired confidentially by attending in their professional characters."[2]

Again: "By the common law of Massachusetts the physician is obliged to state publicly, on the witness stand, whatever may have been told him by his patient, even although involving character or family secrets."

Every New England state has the same law; so, also, Alabama, Delaware, Florida, Georgia, Mississippi, North Carolina, New Jersey, Pennsylvania, South Carolina, Tennessee, Texas, Virginia, West Virginia.

New York, however, follows the Latin precedent and goes even farther, as follows: "No person duly authorized to practice physic and surgery shall be allowed to disclose any information which he acquired in attending a patient in a professional capacity and which was necessary to enable him to act in that capacity."

A similar law governs priests and attorneys. The New York law was subsequently amended so as to allow a physician to testify, in cases of wills, as to the mental or physical condition of the deceased, except confidential communications and such as might disgrace the memory of the patient. The following states have adopted similar laws: Arkansas, California, Colorado, North and South Dakota, Idaho, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Montana, Nebraska, Nevada, Ohio, Oklahoma, Oregon, Utah, Washington, Wisconsin, Wyoming. Eighteen states copy Massachusetts. Twenty-two states follow New York. The remaining states we are unable just now to determine. Such is the law. What are the evils?

Indiscretion, weakness, fear, sin, all seek the family physician as a father confessor. He holds the honor of the patient and the character and social standing of families in his hands. He knows what no other knows; and he often knows what is unknown in the family itself. In every relation of human life the doctor holds, and holds sacred, the secret history of many families, and carries to the grave with him knowledge which would revolutionize the life of whole communities. The mischief of telling is so much greater than the mischief of concealing, that the simplest principle of expediency should forbid the revelation. Every instinct of honor, propriety, decency, is arrayed against it.

Hippocrates laid an obligation on his students that nothing heard in the sick-room should ever go outside it. The wisdom of former ages is only confirmed by the experience of to-day.

Does any one doubt it? Even judges and lawyers acknowledge its force. Says an English judge: "If a medical man were voluntarily to reveal these secrets, to be sure he would be guilty of a breach of honor and of a great indiscretion; but in a court of justice medical men are bound to reveal secrets, when required to do so." Said a Massachusetts lawyer to an unwilling medical witness, before the trial, "You shall have plenty of room to kick!"

Public opinion, not to consider professional opinion, would revile and contemn the man who betrayed confidence. Such opinion says, "You must not tell." The law says, "It may be dishonorable, but you have got to tell." Can any position be more false and more cruel for the honorable man?

I quote the London *Lancet* of May 9, 1896, on the Playfair case: "Never was the question of professional etiquette more forcibly presented. There is no written code to guide the practitioner." "There are [things] which it would be subversive to every moral rule to divulge; there are those which it is his bounden duty to disclose. It is a safe formula that, unless there are overpowering reasons to the contrary, a patient's secret should be held inviolable by his medical adviser, almost, if not quite as binding as the confessional of the Roman Catholic Church. When it involves the commission of crime, morality and justice require the breaking of a confidence." Says Taylor's "Medical Jurisprudence," edition of 1897: "The safer rule for the physician is never, under any circumstances, to reveal the confidence of his patient, and to preserve inviolate any secret obtained in the course of his professional practice."

The doctor in a court of law is in a false position — false in proportion to his sense of honor. Some would go to prison rather than betray a confidence — some would consider (and so say the judges) that the law absolved them. The law should recognize the rights of the patient, the duties of the medical man and the justice due the community.

How can these difficulties be reconciled? We propose the following for consideration:

It shall be considered unprofessional for a physician to divulge anything confided to him by a patient, unless:

(1) With the patient's consent.
(2) To defend himself when accused.
(3) To expose crime.

In all other cases, such professional confidences shall be classed as "privileged communications." It shall be a question of honor whether the physician shall feel it his duty to repeat such a "privileged communication"; if he conscientiously declines, he shall be protected; if he testifies, it shall be before a judge, in private.

[2] Greenleaf on Evidence.

THE WORKINGS OF THE NEW YORK LAW.*

BY WALTER SOREN, ESQ., BROOKLINE, MASS.

THE original form of the New York law in regard to confidential communications between physician and patient (passed at least as early as 1836) is as follows: "A person, duly authorized to practice physic or surgery, shall not be allowed to disclose any information which he acquired in attending a patient, in a professional capacity, and which was necessary to enable him to act in that capacity."

The best way to treat the subject is to illustrate as well as possible by citing cases how the New York courts have construed the most important points in this statute.

In its practical application the statute has been considered as passed solely for the protection of the patient and has been construed somewhat liberally in his favor. Under recent amendments allowing the privilege of secrecy to be waived by the patient or his heirs, no other parties can be allowed to take advantage of the statute if the proper waiver has been made.

Another practical point is that a party at a trial wishing to take advantage of the statute must claim the privilege and show that he is entitled to it, as soon as the objectionable question has been put. If he waits to see whether the answer is favorable to him or not, it is then too late to object in any form.

Theoretically, I shall invite your attention to only three points in this statute which have been passed upon by the higher courts of appeal:

I. What shall be considered to constitute the relation of physician and patient?

II. In any given case, what shall be considered as information "acquired in attending a patient"?

III. What information shall be considered as "necessary" to enable the physician to act as such?

Instead of trying to give a complete answer to any of these questions in abstract form, it has seemed more in accord with the general idea of this paper to cite a number of cases on each point and thus afford a good opportunity for the formation of individual opinion as to the working of the law. The cases from "N. Y." reports are of undoubted authority. Those from Hun and "State" reports are the decisions of inferior courts, but are in accordance with the principles laid down by the higher court and are believed to be good law. Each case should be considered with particular reference to the point under which it is cited, as it has not been fully considered or reported with reference to such other points in it as may seem important on general principles.

The cases are also arranged as nearly as possible with reference to their closeness of application.

I.

First, those referring to the relation of physician and patient:

At the trial of an action involving the validity of a certain will,[1] it appeared that a short time before the execution of the will and the testator's death, the attending physician called another physician, who attended in consultation as to the testator's condition and treatment. One of the parties called the consulting physician as a witness and desired to show by his testimony whether the testator was in a conscious or unconscious condition when examined by him.

It was decided that the relation of physician and patient arose here, under the circumstances, even though the patient might not have known or recognized the consulting physician, and that the consulting physician therefore could not testify as to the condition in which he found the patient.

On an inquisition as to sanity by a jury before commissioners,[2] held some time after the patient had been set free from an asylum, evidence was offered of the opinion of certain physicians who had treated him at the asylum as to his condition when he left. On objection being made on behalf of the patient, it was decided that these physicians could not give their opinion as requested, inasmuch as it was necessarily based upon facts observed while treating him professionally.

At a trial of an action against a life insurance company [3] to recover the amount of the policy, the defence was that the insured had made a false statement in his application as to the health of a brother. It appeared that a month before the application was made, a physician had examined the brother's physical condition at the request of the brother's employer, who received the physician's report and paid him his fee. The physician told the employer that the man was not well enough to continue in business, and also told the brother that he was hopelessly ill, but did not prescribe for the case or give any advice as to its treatment, or have any further connection with it. It was decided, however, that the physician could not be allowed to testify as to the results of the examination, as the patient was entitled to the privilege of secrecy on properly submitting himself to a physical examination, whether or not it was for his own benefit or at his own expense.

At the trial of an action against a railroad company to recover damages for personal injuries received in an accident,[4] the defendant called as a witness a doctor (usually employed by it as an expert), who testified that some two weeks after the accident the attending physician of the plaintiff brought the latter to the office of the witness and asked him to examine the plaintiff and see what was the matter with him. He testified that he made an examination and among other things examined the ribs. He was then asked the question, "Did you find any fractured rib?" It was decided that this might be answered, inasmuch as it was not shown that the witness was requested or expected to treat or prescribe, or to advise respecting treatment, or that he did either.

In a case where the sanity of a person on trial for murder was drawn in question,[5] it appeared that certain physicians had been sent to the jail by the district attorney to make an examination of

* Read at the Annual Meeting of The Massachusetts Medical Society, June 10, 1903.

the prisoner's mental and physical condition. It was decided that they might properly testify as to their opinion of the prisoner's mental condition, merely as they saw him in the cell and in the court-room, but could not testify as to any statements that he made or as to his physical condition.

These cases are sufficient to bring out the most important of the points involved in the first question.

It will be desirable here to mention the following amendment, passed in 1893: "In an action for the recovery of damages for a personal injury, the testimony of a physician or surgeon attached to any hospital, dispensary or other charitable institution, as to information which he acquired in attending a patient in a professional capacity at such hospital, dispensary or charitable institution," shall be taken before a referee, but the court may in its discretion summon him as a witness.

No case has been found involving this amendment, but it does not seem to contain any points of obscurity. Since this amendment was passed one or two cases have been decided in which it might have had some application, but it does not appear to have been taken into account. However, they are of interest on the general subject.

The question arose in one case at the trial of an action brought by a minor against a street railway [6] to recover damages for personal injuries received in an accident. The defendant's counsel called as a witness a physician, who testified that he went with the hospital ambulance to take charge of the plaintiff at the time of the accident, and on the way to the hospital asked him various questions as to how the accident happened, etc.,[7] all, however, in compliance with the rules of the hospital as to his conduct in the treatment of patients. The court decided that the witness might properly state what the plaintiff said to him as to how the accident happened.

Three justices dissented to this opinion, very properly calling attention to the point that the witness distinctly asserted that whatever information he acquired from the patient was in reference to his condition and for the purpose of prescribing for him.

In a somewhat similar case,[8] the physician who attended in the ambulance came to the patient's room in the hospital some ten days after the accident and asked him some questions as to how it happened. The trial judge said, "I think the doctor came there with the assumed authority that a doctor would have in such a place and the communication was privileged." [9] However, it was decided that the relation of physician and patient did not appear under the circumstances to exist in any such sense as to bring the case within the privilege of the statute.

In this case the patient was a child only six or seven years old, and it would seem, under the circumstances, as if the trial judge took the most sensible view. In both the above cases, however, the result would probably have been the same if the amendment had been used.

II.

The second point is on the question of what, in any given case, shall be considered as information acquired in attending a patient.

On the trial of an action in which the physical condition of a certain person during the last year of his life became material,[10] a physician was called as a witness, who testified that he had attended the decedent professionally during the year 1879 and the first few months of 1880. At that time the professional relation ceased, but from then on it appeared that the witness often saw the patient informally and observed his condition in that way until the patient died in November, 1881.

It was decided that the physician might testify as to the patient's condition as it appeared from observations of outward visible facts, open to the sight of any person and seen by him on occasions when not attending in a professional capacity.

The next case is one showing the beginning of the exercise of some ingenuity in avoiding the effect of the statute:

In an action to recover the amount of a life insurance policy,[11] a question arose on a warranty in the application as to the health of the brother of the insured. A physician who had attended the brother professionally and whose whole knowledge of the case was acquired at one interview, was called as a witness by the defence. Of course his testimony as to the results of his examination was inadmissible, but he was asked this question: "What opinion did you form of the case, based on the general sight of the man before you made an examination, or before you had any conversation with him?" It was decided that this question was not admissible, although it related to facts observed by the physician without the necessity or aid of any confidential disclosure, or any physical examination. It was enough that the observation was permitted to the witness in his character of physician and in the due and proper exercise of his calling.

The next case presented an excellent opportunity for the exercise of some ingenuity in evading the operation of the statute, but it was not fully taken advantage of:

At the trial of a case involving the validity of a certain will,[12] where the testamentary capacity of the maker was drawn in question, a physician was called as a witness who had attended the deceased in a professional capacity and also for a considerable period as a friend and not professionally. It appeared from the preliminary questions, however, that the impressions he acquired on the friendly visits necessarily related back to and were influenced by the knowledge he acquired during his professional visits. Of course it was decided that he could not be allowed to testify.

The next two cases, however, seem to have been prepared with great skill:

At the trial of a case in which the validity of a certain deed was drawn in question,[13] a physician was called to testify as to the mental condition of one Eliza Fisher at or about the time when she

executed the deed. It appeared that he had attended her professionally and had also seen her at various times when he was not in attendance for the purpose of treating her professionally He was asked various questions as to her mental condition and requested at the same time to exclude from his mind, in answering, any knowledge or information which he had acquired as to her condition while attending her professionally, and to confine his answers to such knowledge and information as he had obtained of her by seeing her when she was not his patient. Of course the questions were all objected to, but it was decided that they might be answered, because they were so framed as to exclude evidence being given of impressions obtained while the witness was attending his patient in a professional capacity.

At the trial of an indictment for murder,[14] the prosecution called as a witness the physician of the jail where the prisoner had been confined for the preceding six months and proceeded to ascertain his opinion of the mental condition of the prisoner at the time the murder was committed, by putting certain hypothetical questions based upon symptoms which had appeared before the prisoner came to the jail and which had been observed and testified to by other witnesses. The witness was requested, in answering, not to allow his actual knowledge of the case to influence his opinion and replied that it was impossible to do this entirely. As the question was in proper form, however, he was allowed to answer, making what effort he could to comply with the requirements of the question.

It is no more than fair to call attention to the facts that this was a criminal case and also that the relation of physician and patient here was official only. If it had been a civil case the rule would probably have been applied in the same way as in the "Darragh" case just cited.

The foregoing cases give some idea as to what the statute means by the relation of physician and patient; and what information is considered as acquired "while attending the patient."

It remains to examine the point as to what information is considered "necessary" to enable the physician to act as such (and therefore privileged).

Here, more than in the other two points, there has been difference of opinion between the higher and lower courts and also some change in the general opinion since the statute was enacted. It is a good example, too, of how the operation of a statute may be modified and directed by judicial construction. The cases cited will show that while the word "necessary" has received a somewhat broad construction, it is not extended to include in any way matters not directly relating to the patient's mental or physical condition.

The first two are cases where the facts in dispute could not have any effect upon the professional conduct of the practitioner and were not facts regarding the condition of the patient.

III.

WHAT KIND OF INFORMATION SHALL BE CONSIDERED NECESSARY.

At the trial of an action against a railroad company to recover damages for injuries received in an accident,[15] the defendant called the attending physician and asked him this question: "Did the plaintiff state to you on the day when you first called on him that he did not observe the train until he was struck?" This question was objected to, but the court decided that in such a case, nothing the patient could say in regard to his observation of the train could have been either material or useful to the physician in his treatment, and therefore the question might properly be answered.

In another similar case,[16] it was held that the physician who attended a person injured in an accident at a railroad crossing might testify to the statements of his patient of means taken to warn him of the approaching train and which he did not observe untilit was too late.

The next two cases deal with facts relating somewhat to the patient's condition:

At the trial of an action against a mutual benefit association to recover the amount of the policy,[17] it appeared that the deceased had, about a month before he died, in order to get reinstated as a member, made a certificate to the effect that he was in good health. The sole defence to the action was that the certificate was untrue.

It was decided that the physician who attended the insured in his last illness might testify as to the number of calls he made on the deceased, the dates of the calls and that the patient was sick and thus contradict the certificate without disclosing any information intended to be protected by the statute.

At the trial of an action against a railroad [18] to recover damages for personal injuries sustained in an accident, the defendant called as a witness a physician, who testified that the day after the accident the plaintiff called and consulted him. He was then asked if he conversed with her and made an examination of her with regard to her injuries. It was urged in support of this question that it did not appear to call for the disclosure of any information that was necessary to enable the witness to act in a professional capacity. But the court said that the inevitable inference was that the information given to the physician by the patient, whether it related to her injuries or not, would not have been imparted except to aid the witness in prescribing and, therefore, under a liberal construction of the statute, the witness could not state the particular injury as to which the plaintiff consulted him. It will easily be appreciated, too, that the question could not have been answered either Yes or No, without disclosing the fact as to whether the patient was then suffering from her injuries to such an extent as to require treatment.

At the trial of an action brought by a woman against a town to recover damages for personal injuries received by falling on a defective side-

walk,[19] the plaintiff claimed and offered evidence to show that among other severe and serious injuries caused solely by the accident was an umbilical hernia. The defendant then called the plaintiff's family physician as a witness, and he testified that he had attended the plaintiff in a case of childbirth about a year before the accident. At this point the plaintiff's attorney objected, and it appeared that the defendant was about to prove by the witness that the hernia complained of had existed before the accident happened. It was claimed that if the physician discovered the hernia while treating the patient, but did not treat her for it, and the knowledge of its existence was not necessary to enable him to give the treatment he did, he ought to be allowed to testify in regard to it.

The court decided, however, that the witness could not be allowed to testify in regard to the hernia, because the very nature of his employment compelled its disclosure to him, and in this sense the information he acquired as to its existence was "necessary."

It would not be very easy to sum up the result of these and many other cases that might be found in regard to this third point, but it may be put pretty accurately as follows:

Information acquired by a physician in his professional capacity shall be considered necessary to enable him to act, whenever it relates to the patient's mental or physical condition, whether acquired by direct examination or incidentally and whether or not the condition so observed be the particular subject of treatment either at that or at any other time.

HOW THE STATUTE MAY BE WAIVED.

After the statute in its original form had been on the books some forty or fifty years and had worked a great deal of injustice because any one could take advantage of it, the brilliant idea occurred to somebody that as the law was made entirely for the benefit and protection of the patient, it would be no more than fair to allow him to waive it when its operation would work him a great injustice. Accordingly, in 1877 an amendment was made, allowing the patient to waive the privilege.

In about fifteen years more some one conceived the equally brilliant idea for equally obvious reasons, that it would be no more than fair to allow the patient's heirs to waive the privilege, so that the entire amendment now stands substantially in the following form (including in its application two other sections as to clergymen and lawyers):

"The last three sections apply to any examination of a person as a witness unless the provisions thereof are expressly waived by the person confessing, the patient or the client. But a physician or surgeon may upon a trial or examination disclose any information as to the mental or physical condition of a patient who is deceased, which he acquired in attending such patient professionally, except confidential communications and such facts as would tend to disgrace the memory of the patient when, the provisions of Sec. 834 have been expressly waived . . . by the personal representatives of the deceased patient, or (if the validity of the . . . will . . . of such . . . patient is in question), by the executor . . . named in the will, or the surviving husband, widow or any heir at law or next of kin of such deceased, or any other party in interest."

This amendment had a salutary effect in preventing the working of great hardship in many cases where a waiver of the privilege was desirable for the benefit of the patient or of his estate.

But the life insurance companies (who had suffered in some of the cases already cited and of course in many others) were not slow to adopt the plan of putting into all their printed applications a concise but complete waiver of the privilege of the statute, on behalf of the insured or his heirs and all persons claiming under them.

This gave rise to an amendment in 1899 to the effect that the waiver may only be made in open court or by agreement of counsel before trial. However, the waiver so made need not be in any particular form, but may be made by merely calling the physician as a witness and asking him the necessary questions.

It is evident, of course, by this, that it is possible to waive the statute by the conduct of the case in court.

Before calling your attention to a few cases where this has been done somewhat unintentionally, I am going to add to the statement that the statute is solely for the benefit of the patient the corollary that it is not for the protection of criminals. This has been indicated also in one or two of the cases mentioned in the first part of this paper.

It has accordingly been held that in a case where a waiver by the patient or his heirs had become impossible, a physician who had attended the patient might give evidence of facts observed by him tending to show that a crime had been committed and to which ordinarily, without such waiver, he could not be allowed to testify.

But it is no doubt true that if the patient or his heirs were accessible and capable of waiving the privilege, such waiver would have to be made, even in a criminal case, before any evidence could be introduced of any information ordinarily privileged.

The remaining cases to be cited show how the privilege of the statute may be waived at the trial by estoppel, as it were, and are therefore instructive. It will be seen from these, as from some of the cases cited under II, that, naturally enough, attempts are constantly made on behalf of the patient to get the benefit at the trial of the facts constituting the privileged information; and then by the exercise of the privilege, prevent the other side from introducing any evidence in regard to them.

About the time of the commencement of an action against a railway company for injuries sustained in an accident,[20] two physicians attended the plaintiff for the purpose of ascertaining the extent and nature of her injuries. At the trial the plaintiff called one of them as a witness (waiv-

ing the privilege of the statute as to him) and he gave important testimony tending to show that the plaintiff was affected with some spinal trouble as the result of the accident. This opinion was based mainly upon the result of the examination which he had made together with his associate on the occasion referred to. Both had attended together and made a physical examination with special reference to the existence of some disease of the spine as a result of the accident.

When the defence came to putting in their case they wanted to call the other attending physician and allow him to state his opinion. The plaintiff objected to this, but the court held that in such a case the waiver of the privilege as to one consulting physician extended to the whole consultation and the other physician might properly be called upon to state his opinion. The court in this case took occasion to state as a general rule that —

"Where a full disclosure is made with the consent of the patient, the reasons upon which the statute was founded no longer exist and every party to the transaction thus disclosed is relieved from any injunction of secrecy."

At the trial of an action against a railroad to recover damages for personal injuries received in an accident [21] the plaintiff called the physician who had attended at the time of the accident and he testified as to the nature of the injuries. It appeared that three physicians had attended the case, but all at different times, one after another. The defendant then wished to call the other two attending physicians as witnesses, but it was decided that by calling the first physician the plaintiff had only waived the privilege as to him and as to the case as it was when he saw it. But the privilege was not thereby waived as to the subsequent condition of the case and the two physicians called by the defendant could not therefore testify as to the condition of the case when they saw it.

At the trial of an action of tort for personal injuries [22] the plaintiff came on the stand and testified that the defendant shot him in the arm with a rifle and that "Dr. Venner came and put a plaster on it."

The defendant testified that he only struck the plaintiff a blow with the rifle and wished to substantiate this evidence by calling Dr. Venner to testify what his opinion was, at the time when he attended, as to the nature of the wound, claiming that the plaintiff, by his testimony, had waived the privilege, having disclosed and brought in issue the facts as to the nature of the wound. It was decided, however, that the plaintiff had not gone far enough by stating his own observation of the case to waive his privilege of preventing the attending physician from stating his opinion as to the nature of the injury.

It seems pretty evident that so far as can be judged from the records of decided cases the working of the New York law of privileged communications between physician and patient is a little hard on life and accident insurance companies.

It does not seem to have much effect now in contests over questions of testamentary capacity, as any one interested in the estate can waive it.

Nor is it of great service in itself in preventing the disclosure of matters not intimately connected with the physical or mental condition of the patient. This has arisen, however, mainly from the interpretation of the New York court as to what information shall be considered "necessary."

The defence of accident cases is of course much assisted by the amendment allowing hospital physicians and surgeons to testify, and there has also been since 1893 a provision of the code that where an action to recover damages for personal injuries is brought, or expected to be brought, and the case is a proper one for requiring the plaintiff's deposition to be taken, on the plaintiff's motion a judge may before trial order a physical examination to be made at the same time the deposition is taken. The report of the physicians or surgeons making such examination, however, must be made to the court and they cannot be allowed to testify at the trial as to any information acquired at the examination.[23]

Of course this provision cannot be used except in a very few cases, but it is mentioned here for the sake of completeness.

Under the late amendments, the privilege cannot be waived, after the death of the patient, as to confidential communications and such facts as would tend to disgrace his memory. Unfortunately this amendment has not been fully passed upon, so that it can only be conjectured in the light of previous decisions whether the court would decide that "confidential communications" were such only as related to the patient's mental or physical condition.

Before closing, I will call your attention to one more case which illustrates several of the principles already noticed.

A workman employed in a quarry was accidentally struck with a piece of iron on the left side in the region of the heart.[24] The wound was superficial, but quite severe, and he was carried to his home, where he died a week afterwards. He had been carrying an accident policy, but the company refused to pay and the widow brought an action to recover the amount of the policy. At the trial the plaintiff's attorney proved by the testimony of the widow and one or two nurses what symptoms had appeared in the case between the time of the accident and the time of the patient's death.

He then called four physicians who had never seen the case at all and asked them certain hypothetical questions, based upon the evidence which had already been given as to the condition and symptoms of the deceased. These experts all testified that in their opinion the death of the insured was the direct result of being struck by the piece of iron.

The defendant did not cross-examine them at all, but proceeded to call four other physicians and qualified them as experts.

It turned out from the preliminary questions that the last four were the family physician who had attended the case, and three others who had

been called in for assistance and consultation. To each of these, hypothetical questions were put involving the same facts as those put to the plaintiff's experts, but in the following form: "Doctor, please exclude from your mind any knowledge or information you acquired in attending this case professionally and suppose you were called to see a man suffering from a wound in his side such as has been described in this case and found also that he had something of a cough, with an occasional spitting of blood and delirium in the night time; and suppose he died in about a week, while those symptoms continued, what would you say was the cause of his death?" At this the plaintiff's counsel objected; but the court said he had disclosed all the facts himself, so that the answers of the defendant's experts would not tend to disclose any information prohibited by the statute and they might answer and the fact that they really knew something about the case *would only affect the weight of their testimony.* With this permission the defendant's experts proceeded to answer the questions and all testified that in their opinion the patient died of typhoid fever.

Since this paper was delivered an article has appeared in a journal circulated among the medical profession, calling attention to a case in another jurisdiction under a similar law, where manifest injustice was done to a physician who appeared as the defendant in a suit for malpractice. According to the principles contained in the cases above cited, it seems pretty clear that under the New York law the plaintiff in a suit for malpractice would have to prove and thereby disclose so much in regard to his physical condition as to practically waive the privilege of the statute on any matters of importance to the defendant's case.

The obvious lesson to be drawn from the working of the New York law, so far as I have been able to show it, is that any new legislation on the subject of privileged communications would have to be contained in eight or nine separate sections in order to take advantage of the points which have made the amendments to the New York law advisable. It would also be well to avoid, if possible, language giving the court such entire freedom of construction as the word "necessary," which was passed upon in most of the cases cited under III. It is not intended to make this paper controversial and perhaps an apology should be made for the remarks about the malpractice case. It is of course evident that cases of injustice will arise both with and without such a law as prevails in New York. If a new law as to privileged communications is wanted, the question is whether such a law could be framed which prevented more injustice than it caused.

It has often been said that the well-known "Statute of Frauds" did not meet this requirement, yet it is still almost everywhere in force. The fact that they are still amending the New York law, instead of repealing it, is a point in its favor. However, the main question is intended to be left open for the present, for further debate under such light as may be derived from this and other more bountiful sources.

PRIVILEGED COMMUNICATIONS TO PHYSICIANS.[1]

BY FREDERICK J. STIMSON, ESQ., DEDHAM, MASS.

IT was a matter of regret to me that an accident prevented my having the honor of speaking for my profession upon this subject at the annual meeting of The Massachusetts Medical Association; but I have now the advantage of the discussion upon it made by Dr. Cheever and Mr. Soren. I have advisedly changed the title, for the reason that "Privileged Medical Communications" seems to imply that the statutes protecting such are limited to matters medical alone, whereas, at least under some laws, such is not the case.

The papers read at the meeting, as well as the discussion in the BOSTON MEDICAL AND SURGICAL JOURNAL which preceded it, had the valuable result at least of clearing the ground. Probably in the minds of both professions, medical and law, there was considerable haze upon this subject. Many of us had a vague idea that communications *were* privileged when made to a physician in the course of his attendance. This undoubtedly arose from the fact that all judges, under the English common law system of procedure, are clothed with very considerable discretion in their conduct of examinations, particularly cross-examinations, of all witnesses. This discretion is so great that, particularly in states where there is no statute, the judges shape the law. For instance, in Massachusetts, which is among those conservative states still following the common law and rejecting codes, there is, I believe, no instance where a priest has been compelled to divulge the secrets of the confessional. Yet the priest is no more protected by any statutory provision than is the physician. This leads me to the chief of the contribution that I have to make upon the subject — that the question is really, in one of its principal aspects, hinged upon the dispute, with which we lawyers are so familiar, as to the relative advantages of *codes* — that is, statements of the law or of the common law, more or less complete, made by newly drawn-up statutory codes, which intend at least to be

[1] Read before The Massachusetts Medical Society, June 10, 1903.

exhaustive — and the "common law" system, which accepts the English common law as it is, crystallized through a thousand years of court decisions in England and this country, and rarely attempts a new statute, still less a statute which is merely expressive of the common law. The lawyers of this country are still divided on this cardinal point into two schools, and the same is true of the state legislative systems. The older states, particularly those of English origin, stick to the common law, and never attempt to define it, rarely even to improve it by statute. The newer states, especially those where the codes prepared by the late David W. Field have been seriously considered, adopt the other view. The "common law" states are Massachusetts and the New England states, Pennsylvania and the middle states except New York, and the Southern states generally, with one or two notable exceptions, such as Georgia, where they have a code which aims to be so complete as to exclude the necessity of referring to the common law at all. The Field codes of substantive law were generally adopted only in California and the far Western states following her lead, but the Field code of *procedure* was also adopted in New York, and there has been a tendency to codification in New York since. I do not propose here to go into the argument between the two schools. The obvious view of the young Western lawyer, who has not generally had a college education and lives in a town possibly remote from libraries, is that it would be convenient to find all the law in the statutes. We are told in the early lives of Abraham Lincoln that one of the two or three books that he first read and almost learned by heart was a volume of the revised statutes of Indiana — somewhat dry reading, we should think, to-day. The reply to this argument by the common law believers is that the effect of a code is to wipe out all the certainty that we have gained from past history, and to lose the benefit of the infinite number of adjudged cases where the law was decided in the absence of a statute, and where, even now, no statute could possibly be drawn which would apply. Under the common law most cases, after all, have been the subject of judicial decision. Moreover, the vagueness of the discretion left to the judge is possibly of advantage. Under the code system, nothing is certain that is not in the code. No discretion to be strict or to be lenient can possibly be allowed the judge; and until every sentence, every word, every punctuation mark, has been the subject of a court decision, we cannot be certain of what the law is.

Thus it happens that in this matter of privileged communications there has been under the common law very great discretion exercised by the judges, extending, as I have said, in the case of priests, at least, to a complete privilege, and probably in the case of physicians, to a very considerable protection. This protection is given, it is true, at the court's discretion, but is the more adjustable to the reason of each case by that very fact; and at least one thing is clear — that if we are to have a statute on the subject, that statute must necessarily be a rod of iron. It must apply to all cases equally; and nothing on the one side of the line can be allowed and nothing on the other side can be excluded. No one, for instance, contends that the privilege of physicians should be extended to cloak crime, and yet it is extremely probable that, if the statute were passed, there might be some other cases where the admission of a physician's testimony would be for the public advantage; and on the other hand, even when the privilege is extended in civil matters only, it should certainly not go so far as to prevent a physician from testifying as to the mental condition of a deceased testator in a contest over a will.

In short, I believe that the general question will be largely determined, at least by lawyers, according as they believe or do not believe in general statutory codes.

Coming now to the concrete matters. It is clear, as I have said, that the following points are fairly established: (1) The lawyer at common law has a privilege the physician and priest have not; (2) the privilege should rarely, if ever, be extended to criminal cases; (3) the privilege exists for the benefit of the patient or client, and not for that of the physician or lawyer. There are other points which are very uncertain, at least in states where they have a statute upon the subject; for example, whether the privilege extends to actual communications or also to matters of observation which fell under the notice of the physician while occupying the relation of medical adviser to the patient; whether the patient must, in fact, have employed the physician or have known that he was so employed; whether and under what circumstances the privilege may be waived.

The statutes, in so far as they have been adopted, fall also into several classes. According to the latest textbook on the subject, that of Mr. Arthur M. Taylor of New York, they have not been adopted in New England and the middle states, except New York and Pennsylvania; but the Pennsylvania statute is very moderate, applying only to civil cases; in the South they have been adopted only by North Carolina; but in the middle West they have been adopted by all the states except Illinois; in the states west of the Missouri River by all the states and territoires except New Mexico — twenty-five states and territories in all have a statute, but the tendency, even in these states, is not always consistently in favor of a professional privilege to physicians. Minnesota has recently adopted and Michigan proposed most extraordinary statutes, one providing that no physician shall, in matrimonial causes, be protected from testifying as to the existence of a sexual disease, and the other (which, however, failed for the moment to pass), providing that no one could get married without a certificate of his family physician

that he or she was free from epilepsy, consumption or sexual diseases generally, and that in no such case should the doctor have any privilege whatever. It is also important to notice that the statutes very generally apply only to licensed physicians or surgeons, though, as we know, the tendency to license persons not regular physicians — osteopathists or Christian Science people — is very largely increasing in the more radical states. Generally the privilege only applies to such information as was necessary to enable the physician or surgeon to act in his professional capacity. Such is the New York statute; but a court of Pennsylvania, notwithstanding its statute did not go nearly so far as that of New York, made a very sensible decision that matters outside such professional information, when confided to the doctor by the patient, especially in answer to the doctor's questions, were also privileged — a most excellent example, by the way, of the advantage of the common law over the code: the Pennsylvania court, having no code law upon this point, could make such a decision, while a New York court could not. Generally the statute reads that a physician shall not *be allowed* to disclose such information, but in some states it is only that he shall not be compelled, and in most states, as I have said before, it may be waived, not by the physician, but by the patient or party to the suit. The restriction of the privilege to civil cases exists in only a few states having the statute. In my opinion the wisest law of all is that of North Carolina, which, while creating the privilege, says that the presiding judge may compel disclosure of knowledge professionally obtained, etc., if in his opinion the same is necessary to a proper administration of justice. Practically, this is the common law.

The relation of physician and patient must, of course, exist. The mere fact that a man is a physician confers no privilege, but it is usually immaterial whether the physician was called or employed by the patient or by some one else. A physician who goes really to get evidence, not employed by the patient, although he may give some professional treatment, commonly acquires no privilege, especially when the physician is wholly paid by a third party. One physician may, however, call in another and impart to him the privilege. In Ohio, Indiana and in other states the statute extends to all matters observed by the physician, although not confided to him by the patient or not necessarily matters relating to the treatment. For instance, in Arkansas, where an unmarried woman told her physician that the father of her child had not promised to marry her, the communication was not held to be privileged, as it had nothing to do with her professional treatment. This rule is usually in opposition to the statute contended for by Dr. Cheever, which protects only the disclosure of any matters tending to cast disgrace upon the person treated. A physician was not required, in Missouri, to state that his patient was drunk when he called upon him for professional services. In no case is there any privilege in suits by the patient against the physician for malpractice.

Let us now consider the usual cases in which the question of the physician's privilege arises. These are: (1) Criminal cases where the patient is the criminal; (2) criminal cases where the patient is not the criminal but the person injured; (3) actions for damages for personal injuries by the patient; (4) will contests; (5) actions by the beneficiary of insurance policies; (6) suits between physician and patient. Let us leave the question of statute or common law, but consider, broadly stated and in popular language, how we should like the law to be in each of these classes of cases.

(1) Criminal cases where the patient is the criminal. I can see no reason, nor do I believe that the medical profession will differ from me, to use the physician's privilege to protect crime. We all recognize the ethical duty of the physician not to tell. No one claims that he should run to the nearest police officer; but these considerations are matters of professional honor and there they may well be left. When the patient, long after he is well, is actually apprehended and brought into court on a charge of murder, or even assault, it is clear that the highest interests of the state require that the physician's knowledge should not be used to cloak the crime. Certainly that is true in cases of murder, but in the lighter cases — take the example of assault and battery — it is pretty clear that a man who is seriously injured will not risk his life by failing to consult a physician when the punishment for the crime itself is so slight. And for the extreme example, does any one claim that the doctor who set the leg of John Wilkes Booth, after the murder of Abraham Lincoln, should have been prohibited from testifying to the facts? Was he not in fact sentenced for life because he did not reveal the fact?

(2) Criminal cases where the patient is not the criminal, but the person injured. In this case there seems no reason whatever why the physician's testimony should not be required.

(3) Actions for damages for personal injuries by the patient. This is perhaps the only case subject to any doubt, but after all, why should the patient be protected? If his injury is really trivial and the person injured intends to maintain a fraudulent claim for large damages, there does not seem much injustice in the end in making him go to a physician at his own risk. Moreover, it is always to be remembered that it is difficult for him to refuse seeing a physician sent by the defendant. If, on the other hand, the person is seriously injured he will certainly go to a physician and that physician will certainly testify to his benefit. In fact, experience shows that physicians, perhaps properly, are more than ready to testify on their patient's side of the case.

(4) Will contests. In this case it is perfectly clear that there should be no privilege. To begin with, the patient is dead. Even in New

York there has been a desire and an attempt by the courts to alter the law in this particular, so that a physician may only not be required to testify, after the decease of his patient, to anything bringing disgrace upon him or his family. But the matters which result in the annulment of wills are not usually those which bring disgrace upon the patient or his family, except where that disgrace is richly deserved. Wills are rarely affected by the physical condition of the patient. They are either affected by outside conditions or by the patient's mental condition, which is surely proper matter of evidence.

(5) Actions by the beneficiaries of insurance policies. All life insurance companies now require the applicant for a policy to see their own physician, but under the New York statute even he is prohibited from testifying. There might be some reason for this on the ground of estoppel: if he allows the applicant to get a policy, he could logically be prevented from saying that he ought not to have had a policy; but as a matter of fact, it is well known that the New York statute, in effect, works a fraud upon life insurance companies, and if the family physician knows that the policy holder is subject to an incurable disease and, notwithstanding, he gets a life policy by concealment of that fact, under what ethical principle is the physician not to testify after his death, thus making a fraud effectual?

(6) Suits between physician and patient. Under the common law there is no privilege in suits for malpractice, while suits by a physician for his fee are somewhat rare in the higher orders of the profession. Certainly it is not for the interest of the physician, at least, to have the privilege maintained in this latter case.

Finally, there is a great class of cases, likely more and more to get into the courts, in matters of marriage, divorce or sometimes wills, where the physical condition and the just or temperate life of some person is concerned. I have not made a definite class of these, for the reason that they might come in almost any of the divisions above set forth. Probably we all know cases where the testimony of the physician has been of great importance, as in matters of justifiable breach of promise. Those wishing to go into the subject may refer to a very able article by Professor Huberich of the University of Texas, in a recent number of the *Harvard Law Review*. But these are all peculiar cases where the discretion of the judge, acting under the wise liberality of the common law, may be relied upon to protect both the patient and the physician. No statute can be drawn which may be safely applied to such delicate matters short of the absolute exclusion of all testimony by physicans in all cases. I have said enough to show that in my opinion this, at least, is unwise.

My own conclusion is, therefore, both that in most cases the common law stands right, and that it is wiser in all to leave the whole matter to the common law. A significant argument for this is shown in the very fact that Mr. Soren has found it necessary to fill some twenty pages with an account of cases where it has been necessary for the supreme tribunal of New York to decide what the statute meant. All these are the consequences of the adoption of a statute. During the same period very few such cases have troubled the courts of Massachusetts and the courts of New England, for under the common law the rule is in most cases clear. And there has recently been a distinct check to the tendency to adopt statutes upon this subject. I find that, while some twenty or twenty-five states copied, as they usually do, the statute of New York when it was adopted, since 1891 there has been no statute in any state of the United States except the very reasonable one already mentioned in Pennsylvania, and an extraordinary statute in Iowa which absolutely prohibits physicians from disclosing any communications given in professional confidence, and which applies as well to stenographers or confidential clerks. Indeed it may be doubted whether the reasons for such a statute do not apply as well to the case, for instance, of a confidential clerk or a trustee as of a physician.

The reason of the privilege given the lawyer rests on quite a different basis. One goes to him for the express purpose of being defended in the courts. We all know that the ethical position of the lawyer defending a person known to him to be a criminal has been a commonplace of debate for centuries. Nevertheless, it is generally accepted now, if only on the broad ground that it is by no means easy always to tell whether a man is a criminal or not, and that, even if he be a criminal, he is entitled to counsel, if only for the purpose of determining the degree or grade of his offence. This, therefore, is a mere rule of the game in the courts. But a criminal does not, in the ordinary course of events, have to go to a physician; and in ninety-nine cases out of a hundred what the physician testifies to is of momentous consequence, civil and criminal, and often no other person can be conversant with the facts.

If any statute is adopted I should recommend a combination of the laws of Pennsylvania and North Carolina; that is, adopt the Pennsylvania principle that the privilege extends only to civil cases, and this with the exception of the competency of persons making a will, and the very luminous phraseology of the North Carolina statute, which substantially states the common law, that is, it allows the judge to determine when the communication by physicians of knowledge acquired while attending the patient is necessary for a proper administration of justice.

Many legal abuses have grown up and many bad decisions have been rendered in this country, I regret to say, from the plain ignorance, that is, the absence of historical legal education on the part of the judges. Notably this has been true in the great human interests affecting labor and capital, and those recent combinations commonly known as trusts. Two great evils — the election of ignorant judges and the clothing

of petty courts with high chancery powers — have largely been responsible for the abuse known as government by injunction and the objectionable powers of trusts; and it is more than probable that, in matters of evidence, many judges have rudely compelled the disclosure of professional secrets which in no sense really pertain to the necessary administration of justice. This is, indeed, one of the arguments for the code, that it brings to the notice even of an unlettered judge more principles of the common law than he might otherwise be familiar with; but for Massachusetts, at least in this matter of privileged communications, I should prefer to rest, as we do now, upon the definiteness and the elasticity of the common law, the good sense of the judges and the honor of the medical profession.

Clinical Department.

ECHINOCOCCUS CYSTS OF THE LIVER AND LUNGS.

BY ARTHUR K. STONE, M.D., BOSTON.

THE following case was brought to Medical Room of the Out-patient Department of the Massachusetts General Hospital, and from thence it was transferred to the service of Dr. Chas. B. Porter, who immediately operated. The patient lived four days. The important portions of the various records are appended.

The patient was an Armenian who had come to the United States seven years before, during which time he had lived and worked in Milford, Mass. So far as could be ascertained, he had always considered himself well until ten weeks before his coming to the hospital. Dr. Gaiolzakyan, who accompanied the patient, when asked about the habits of the Armenian peasants, stated that hydatid disease was not common in Armenia nor was there any special opportunity for exposure for the people living in the Armenian villages.

For ten weeks there had been progressive loss of strength and weight, accompanied by pain in the epigastric region. Two weeks after the appearance of the symptoms they had become so severe that the patient had been obliged to stop work. When the presence of a tumor was first noticed could not be ascertained. The ordinary symptoms of fever had been present, but no chill. In the past three weeks the epigastric pain had been very severe and the weakness and emaciation had progressed rapidly. Throughout the sickness there had been no symptoms of dyspepsia and no vomiting. The bowels had moved without difficulty and on the day before there had appeared a tendency to diarrhea. The patient was much exhausted by his efforts in coming to the hospital.

Physical examination showed a well-developed man, much emaciated, pale, and sweating profusely. His tongue was dry and coated. There were no glandular enlargements visible. The sclera showed a very slight yellowish tinge. The temperature was 96° F. A stained preparation of the blood showed no marked leucocytosis. A blood count some hours later gave 1,600 whites. The urine was high in color, acid, 1,025. Albumin present, 1-10 to 1-8%. Bile was present in small amount. The sediment showed numerous brown granular casts, also a few normal blood globules. The sounds were weak, but otherwise the heart was practically normal, as also appeared to be the left lung.

The lower portion of the right chest was bulging. There was flatness from the fourth rib in front to four fingers' breadths below the costal margin. Below the fourth interspace in front and the mid-scapular in the back there was absence of fremitus and respiratory murmur. Below the ribs, extending nearly to the median line, was a convex bulging tumor. On inspiration there was a palpable crepitus, and a loud friction rub was to be heard over the outer portion of the tumor. Over the convexity of the mass there was a doubtful sense of fluctuation. The edge of the liver and the whole surface of the mass presenting below the ribs felt smooth and hard. The diaphragm phenomenon was absent on the right side, but well marked on the left.

The abdomen was otherwise normal, there being no sign of ascites, so that the lower portion appeared flat and depressed as compared to the upper portion. In spite of the fact that he was an Armenian, the spleen was not palpable.

The examination of the right back showed dullness beginning at two inches below the spine of the scapular, quickly becoming flat. Respiration and fremitus were diminished and lost below the angle of the scapular. Above the dullness the respiration was harsh but of diminished intensity. Signs in the left side of the back were practically normal.

With the left hand at the back, pressure over the tumor was transmitted through to the under hand, also a faint feeling of trembling as of an over-distended cyst. It was evident that we had to do with a greatly enlarged liver and with a tumor of its anterior surface.

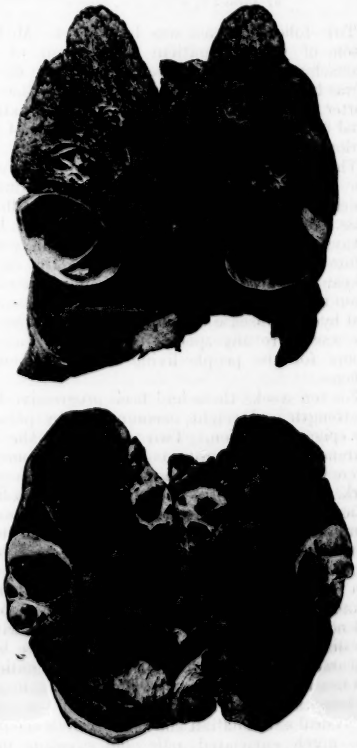
The cause evidently had begun to obstruct the outflow of bile, as shown by the slight jaundice. There were evidences of perihepatitis and probable peritonitis present, but they were evidently secondary in character and of recent origin. Cancer was hardly to be considered, from the absence of all symptoms of indigestion and the rapidity of the development. Primary abscess of the liver could not be eliminated, but was made improbable from the absence of history pointing to intestinal infection. Hydatid disease could not be eliminated but did not seem probable from the history. This left the rare cystic disease of the liver, against which nothing could be urged but its rarity. There were, of course, evidences of secondary imflammatory process present.

Immediate operation was deemed advisable, and Dr. C. B. Porter operated, making an incision through the abdominal wall over the most prom-

inent portion of the tumor and parallel to the costal margin. A small amount of bloody fluid was found in the cavity, which proved sterile on culture. The tumor presenting in the wound consisted entirely of the enlarged liver, which appeared dark and distended and softer than normal. On the second attempt, the aspirating needle found purulent material at a depth of about two inches. The cavity thus found was quickly opened by knife and dilators. The contents of the cavity gushed out, showing the pressure under which they had been retained. The amount of the escaping material, blood, pus and gelatinous material was estimated at about four quarts. In the escaping fluid were innumerable cysts from the size of a pea to those two inches in diameter. As the hemorrhage was excessive, the cavity had to be packed with gauze after cleansing as thoroughly as possible.

The patient, though in poor condition after the operation, made a good recovery from the ether.

The following day the patient felt much better than before the operation, and the ooze from the wound, which at first was considerable, stopped. Early on the second day after the operation the patient suddenly became delirious, pulse 150; temperature 104.5°. Abdomen was flat; there was a large movement following the administration of calomel. There was flatness and friction sounds to be heard at the base of the chest on the right side. No signs of consolidation, however, developed and the general condition somewhat improved. The wound continued in good condition and there was no distention of the intestines. At noon, the fourth day after the operation, the patient's condition suddenly changed for the worse and death followed.



ABSTRACT OF AUTOPSY RECORDS, CLINICO-PATHOLOGICAL LABORATORY, MASSACHUSETTS GENERAL HOSPITAL.

Autopsy No. 981, Dec. 13, 1902.

The liver is of about normal size, and in the right lobe there is a large, irregular-shaped cavity probably 15 cm. in diameter. This cavity, for the most part, has a rough, irregular lining composed chiefly of a patchy layer 2 or 3 mm. thick, of dirty greenish gray, somewhat friable, finely granular material. Adherent to this in places are plaques and patches of a dense but friable dirty grayish, opaque, tough substance. The plaques of this substance are 2 or 3 mm. in thickness and are not easily removed from the lining of the cavity. In places the lining of the cavity resembles the mucous membrane of the gall ducts and presents the appearances of being formed by the walls of greatly distended gall ducts more or less reddish discolored. In fact, a close examination and dissection shows that these portions of the lining resembling distended gall ducts are undoubtedly continuous with the hepatic duct of the liver. This was followed below the opening of the cystic duct and found to be apparently of wider circumference than normal. The cavity of the liver lies in immediate relationship with the diaphragm and the diaphragm is adherent to the liver and forms probably a part of the wall of the cavity superiorly. The lining of the cavity seems to be separated from the liver substance by a thin layer of connective tissue. In the superior wall of the cavity and in the midst of a considerable amount of what appears to be inflammatory tissue adherent to the surface of the liver are two abscesses filled with white, thick pus, the largest about 12 mm. in diameter. In the neighboring liver tissue several much smaller abscesses are apparent. The liver not extensively cut up, in order to preserve the specimen for teaching purposes. Portions of the wall of the cavity, including adjacent liver substance, preserved for microscopical examination.

Lungs.— In each lung there are cystic structures in the midst of the pulmonary tissue and bulging outwardly beneath the pleura. Where they bulge the most, these cystic structures have a grayish, translucent wall, apparently formed of little more than the pleura. The dimensions of these cystic structures and their situations are as follows:

Right Lung. — Median lobe. Cystic structures 3 cm. in diameter. In the inferior lobe of

LUNGS FROM THE CASE OF ECHINOCOCCUS CYSTS OF THE LIVER AND LUNGS. (Photographs by Dr. A. H. Gould.)

the right lung a large cystic structure 7 cm. in diameter. In the superior lobe of the left lung a cystic structure about 4½ cm. in diameter. In the neighborhood of these a collapsed cystic structure probably 3 cm. in diameter. In the inferior lobe of the left lung another apparently multilocular cystic structure probably 3 cm. in diameter. In the inferior lobe of the left lung another apparently multilocular cystic structure about 6 cm. in diameter. At the base of the same lung, not bulging to the pleural surface, are two cysts, 1½ and 1 cm. respectively in diameter. These are filled with a clear fluid and possess a white gelatinous lining in the form of a layer about 1 mm. thick. This is readily removable, leaving a smooth surface beneath, apparently formed by a thin layer of connective tissue. No evidence of pneumonia or acute pleurisy. Lungs preserved in formalin for further examination.

BACTERIOLOGICAL REPORT.

Coverglass from the purulent material in the liver shows no bacteria.

MICROSCOPICAL EXAMINATION.

Sections of the wall of cysts in lung show the kitinous layer with brood capsules containing scolices adherent.

Sections of liver bordering upon the cystic cavity show chronic inflammatory changes. In one section foci of necrotic material are present.

Spleen. — An area of necrosis in the section, which area probably corresponds to a suspected infarct.

ANATOMICAL DIAGNOSIS.

Evacuated echinococcus cyst of the liver. Small abscesses of the liver. Echinococcus cysts of the lungs.

There have been four other cases of echinococcus cyst operated upon at the hospital since 1890. Three of these have been men and one a woman. Strangely enough, one of these patients was an Armenian, who had lived in this country for six or seven years. Thus two out of five cases have developed in a people who make up a very small portion of the community. Another patient was a Russian Jew; a third was an American sailor who had, however, never been in Iceland, but had "always had a dog on board." The woman alone was a native of Iceland and had had symptoms of pain in the side seven years before her coming to the hospital, and five years previously she had had a cyst of the liver opened.

Of diagnostic symptoms there was little to be gained from the histories. Pain in two cases came on only within six weeks of the time of operation. In one there was marked nausea lasting for six weeks and in two cases the symptoms developed suddenly, one as the result of acute inflammatory processes and the other brought on by a blow which ruptured the cyst, which had apparently given no previous symptoms. In one case the tumor, which was sub-hepatic, had been noticed for thirteen months. In the woman's case the pain had developed three years after the first operation. The pain had started at the border of the ribs and radiated upwards towards the axilla and would often last for half an hour at a time. Indigestion, nausea and vomiting were not complained of.

Four of the five cases here mentioned recovered from their operations. These cases are therefore of interest in that two of them occurred in Armenians, a people of whose susceptibility to echinococcus infection we have no statistics. In four of the cases pain was the first most pronounced symptom which attracted attention. In the case given above in detail the extent of the lesions in both lungs, which gave rise to no symptoms, together with the large cyst in the liver, makes the case quite unusual.

Reports of Societies.

SURGICAL SECTION OF THE AMERICAN MEDICAL ASSOCIATION.

NEW ORLEANS, LA., MAY 5 TO 8, 1903.

(Concluded from No. 9, page 242.)

THIRD DAY (*Concluded*).

DR. HENRY A. CHRISTIAN, Boston, reported a case of

EPITHELIOMA OF THE CAULIFLOWER TYPE OF THE BACK OF THE HAND,

which examination previous to the beginning of treatment had proved to be a true example of this condition. Serial examinations during the progress of degeneration showed that the cells died, were surrounded by granular cells and were destroyed. During the operation a portion of the hand which had been supposed to be non-carcinomatous was protected by a lead sheet and this afterwards became infected. During the process no polymorphic nuclear leucocytes were present and he did not look upon the process as one of fatty degeneration.

DR. EDWARD H. NICHOLS, Boston, stated that he believed many cases of epithelioma were reported as cured, when in reality it was simply a healing over of the skin surface. The action of the x-ray, he believed, was that of a mild irritant, thus producing increase in the epithelial cells and later disintegration. He also referred to the fact that the x-ray will produce epithelioma, a case being reported of an operator in Boston who lost three fingers from one hand and two from the other. Operative treatment was recommended in all cases where possible, and in some cases it was thought secondary treatment by the x-ray would be beneficial.

DR. FRED B. LUND, Boston, reported several cases of epithelioma of the face of the rodent ulcer type, which had been benefited by the x-ray treatment, and in the cases in which recurrence had occurred there had usually been glandular involvement. In a case of recurrent carcinoma of the breast he had removed the

growth several times under local anesthesia and the patient was finally subjected to the x-ray treatment without any apparent result, and the opinion was expressed that it had very little effect upon malignant growths.

DR. JOHN W. BRANDAU, Clarksville, Tenn., reported two cases of cancer of the cervix treated by the x-ray, in which the pain disappeared and the growth underwent rapid degeneration.

DR. WILLARD, in closing, stated that he believed a blue medium would increase the quantity of the ultra-violet rays and thus be of benefit in the x-ray treatment of tubercular joints. He believed that the sunlight, Finsen light and x-ray would have to be used for at least five years before any definite conclusions could be reached, and recommended mechanical fixation of the joint in addition to the treatment by the other methods. He also believed that bringing the patients out of the darkness and giving them good food had much to do with their improvement.

DR. STEWART, in closing, stated that he did not think leucocytosis was a very important factor in the degeneration of the epithelioma, and reported two other cases in which this did not occur, but the occurrence of vascularization he thought was singular. He reported a case of tuberculosis of the shoulder joint, in which, during the first two months of treatment by the x-ray, very little result was obtained, but in from eighteen to twenty-four months good influence over the tubercular process was obtained.

DR. JOHN E. SUMMERS, JR., Omaha, Neb., read a paper entitled

VARIX OF THE INFERIOR MESENTERIC VEIN, COMPLICATED BY CHRONIC ULCERATIVE COLITIS; OPERATION.

In the case reported there was a chronic ulceration of the rectum and sigmoid flexure of the colon, accompanied by the usual clinical signs and demonstrated by ocular inspection, which he was not able to state positively was the effect or cause of the varix of the inferior mesenteric, but believed it to be the latter.

DR. CHARLES A. POWERS of Denver read a paper on

CONGENITAL DISLOCATION OF THE RADIUS.

The patient was a boy of thirteen years, in whom the left upper extremity had been from birth materially shorter than its fellow, the bones of the forearm being fixed in extreme pronation with inability to supinate. The elongated left radius was dislocated upward, forward and outward, lying on the outer and anterior aspect of the humerus. Photographs and x-ray pictures showed the condition.

DR. JOHN P. LORD, Omaha, Neb., read a paper entitled

ACUTE EPIPHYSISITIS OF THE HEAD OF THE FEMUR, CAUSING A CONDITION SUBSEQUENTLY SIMULATING CONGENITAL MISPLACEMENT,

in which he reported the case of a child who had an abscess over the hip at the age of sixteen months, up to which time he was supposed to be normal. As a differential factor in the diagnosis of these conditions he mentioned the fact that in the congenital deformity the head of the femur is against the ilium, while in the pathological condition it is far removed from the pelvis.

DR. WISNER R. TOWNSEND, New York, felt that the most important point was to keep the thigh abducted and prevent irritation, and recommended that the thigh be placed in a plaster of Paris bandage instead of a leather support or splints.

THIRD DAY — AFTERNOON SESSION.

DR. H. EARLES, Milwaukee, Wis., read a paper entitled

NECESSITY FOR MORE CARE IN THE TREATMENT OF SKULL FRACTURES,

which he summed up as follows:

(1) Fractures of the skull are not always recognized as such until too late. (2) When not properly treated at or about the time of fracture, they frequently result in death, and if not in death, in serious remote consequences. (3) When properly treated they usually terminate satisfactorily, and with ordinary care and cleanliness fractures of the skull may be successfully treated by the average surgeon and under ordinary conditions.

DR. SULLIVAN, Chicago, recommended operation in all cases of compound fracture of the skull, and that simple fractures should be kept under observation and operation performed so soon as motor symptoms developed. If sepsis occurs a median incision should be made and drainage established.

DR. B. B. DAVIS, Omaha, Neb., referred to the fact that very often there were extensive injuries to the substance of the brain with very little injury to the bone, and he believed the two things to be considered in deciding whether or not to do an operation were (1): Is there any danger if we do not do the operation? and (2) Are we going to leave the patient in a bad condition if we do it? The operation should not be done unless absolutely necessary, as cicatricial tissue is liable to form and cause subsequent trouble.

DR. JAMES B. BULLITT, Louisville, Ky., read a paper entitled

EPISPADIAS; REPORT OF A CASE TREATED BY A MODIFICATION OF CANTWELL'S METHOD,

in which he stated that, while he believed the operation as described by Cantwell in 1898 to be an almost ideal operation, he felt that the transplantation of the newly-formed urethra beneath the penis in its normal position was an improvement and had employed this modification in his case. With the exception of a small fistula about the size of a pinhead, the wound healed and the patient was able to retain his urine for several hours.

DR. RUDOLPH MATAS, New Orleans, La., read a paper entitled

CICATRICIAL ANCHYLOSIS OF THE JAWS; A CONTRIBUTION TO ITS OPERATIVE TREATMENT.

The teeth were horizontal to the jaw, and they would not open to a sufficient extent to admit the blade of a knife, the patient being compelled to live entirely on broths and milk. The cicatricial tissue was first removed and then two bilateral flaps of the skin turned in to take the place of the mucous membrane. Very satisfactory results were obtained by this method, and the patient improved considerably.

DR. J. B. MURPHY, Chicago, reported two cases, in the first of which, after the incision through the fibrous growth and the removal of the mass, a flap was turned down on the neck, the cutaneous surface being on the inside, and a good recovery ensued without much disfigurement. The second case followed the removal of a large angioma, the teeth standing at an angle with the side of the mouth, and after doing the same operation a fairly movable jaw was secured.

DR. ARTHUR DEAN BEVAN, Chicago, read a paper entitled

FURTHER CONTRIBUTION TO THE SURGERY OF THE UNDESCENDED TESTICLE,

in which he expressed the belief that this condition occurred much more frequently than was generally supposed, and called attention to the following possible dangers of leaving the undescended testicle in its original position: (1) Hernia; (2) traumatism; (3) gangrene through twisting of the cord; (4) inflammation of the misplaced testicle; (5) malignant disease.

DR. J. B. MURPHY, Chicago, read a paper entitled

SURGERY OF THE URINARY TRACT IN THE FEMALE, EXPERIMENTAL AND CLINICAL,

in which he dwelt particularly upon the conditions of pyelonephritis, hydronephrosis and pyonephrosis. In all cases of infection of the kidney he recommended removal of the capsule and division of the kidney. He directed attention to the fact that with two healthy kidneys there was about four times the necessary renal secreting surface, and recommended the removal of the kidney in a secondary operation if the primary operation did not relieve the infection. He laid particular stress on the necessity, in operations on the pelvis, of making a large incision and bringing out the kidney, in order that you could better see to work, and directed attention to an incision through the bladder which he had found valuable, as the wound heals very quickly and it is a convenient route.

DR. ARCHIBALD MCLAREN, St. Paul, Minn., felt that the operation suggested by Dr. Murphy was very valuable in pyelonephritis. He stated that in several cases upon which he had operated for stone in the kidney, where he was sure perfect aseptic conditions prevailed, the operation was followed by a curious diphtheritic inflammation of the pelvis, which later necessitated the removal of the kidney.

DR. GEORGE GOODHUE, Dayton, Ohio, thought that if we were able to ascertain that the patient had one healthy kidney, by means of segregation it was better to remove the kidney than to subject the patient to repeated operations, with the consequent dangers of anesthetics and emboli.

DR. ALBERT M. TAGERT, Chicago, reported a case of movable kidney upon which he had operated one week after labor, the patient at that time having a temperature of 102° to 104°. There was very little secretion of the urine, and trouble with the other kidney was suspected. Everything went well for two weeks, when the nurse reported that she could not wash it out through the bladder. Upon introduction of the catheter he succeeded in opening the ureter, and the temperature fell to normal in five or six hours.

DR. RUDOLPH MATAS, New Orleans, stated that he believed there was no field of surgery in which conservatism was of more value than in the surgery of the kidney. He felt that in any infection of the kidney personal equation and the capacity of the operator must always be taken into consideration, and that when one has not had very much experience it may be better to remove the kidney at the primary operation.

DR. J. B. MURPHY, Chicago, in closing, recommended drainage through the cortex in connection with the operation for removal of a portion of the kidney or in an operation for stone in the kidney. The advantages of drainage as a primary operation instead of doing a nephrectomy are not that it is easier, but because a primary nephrectomy done according to Kister produces a mortality of from 23% to 50%, according to the conditions preceding operation, while with a secondary nephrectomy following drainage the mortality is almost nothing.

DR. A. H. LEVINGS, Milwaukee, Wis., read a paper entitled

TUBERCULOSIS OF THE MAMMARY GLAND,

in which he stated that the condition was almost exclusively confined to women, usually occurring between the ages of twenty and thirty-five years, during the activity of the gland. Nearly one-half of the women affected with the condition have borne children; it frequently occurs during pregnancy, and is superinduced by a weakened, anemic state. It does not appear to be dependent upon the pre-existence of the disease in any other portion of the body, and if it is secondary to a tubercular process elsewhere, the focus may be situated in the lungs, skin or some distant part of the body, the route of the infection being in many instances through the lungs. The differential diagnosis between this condition and carcinoma is not always easy, and prompt operative treatment should be instituted.

DR. B. B. DAVIS, Omaha, Neb., reported a case occurring in a young woman about thirty years of age, in which there was considerable involvement of the axillary glands with perfora-

tion and fistula, there being a history of a discharge containing tubercle bacilli.

DR. ANDREW WADE MORTON, of California, stated that he had recently made the diagnosis by the injection of tuberculin, with subsequent confirmation by pathological examination.

DR. A. H. LEVINGS, in closing, stated that he believed the reason so few cases of tuberculosis of the mammary glands were reported was because the condition was diagnosed as carcinoma. In regard to the treatment by curetting, he felt that the infection was confined chiefly to the pyogenic membrane, and if this could be eradicated one would get rid of the infection.

FOURTH DAY — MORNING SESSION.

DR. LUTHER SEXTON, New Orleans, read a paper on the

TREATMENT OF FRACTURES OF THE FEMUR IN PLASTER OF PARIS CASTS,

in which he called attention to the difficulty of approximating the fragments of the bone and retaining them in proper apposition, the greatest difficulty being to prevent shortening and displacement. He believed that plaster of Paris bandages were preferable to the side splint for this purpose, and described the technique in detail, laying stress upon the necessity for bringing the plaster of Paris high up around the pelvis. The method is cleanly, the bandage cannot get out of place, and good results will follow its perfect application.

DR. JOHN P. LORD, Omaha, Neb., while he did not think that all fractures of the femur should be treated by this method, particularly those below the trochanter, felt that it was particularly applicable for the treatment of intracapsular fractures, extension being used in addition to the plaster, if necessary, the most important point being to get the fragments of the bone in proper apposition and then maintain them there by proper dressing.

DR. ALBERT E. GRANT, Denver, Col., referred to the remarks of Dr. Allis in regard to the difficulty of maintaining correct apposition of the parts, and the necessity for cutting down the ends, and the consequent suggestion of Dr. Lane of the cutting down and wiring of the fragments, and stated that he had found this practice of value in fractures of the elbow joint. The best results, he believed, would be obtained by applying both some method of extension and a fixed apparatus around the limb. He did not think that the plaster should be applied until three or four days after the injury, when all inflammation had subsided, and recommended that the silicate of potash be employed in lieu of the plaster, as it is very light, the only disadvantage being that it requires more time to harden.

DR. ANDREWS of Mahnhata, felt that much better results would be secured from the use of the plaster of Paris dressing than from complicated body splints, and believed that it should be applied after the inflammation had subsided.

DR. SEXTON, in closing the discussion, exhibited one of his patients, who was an engineer, who, in jumping from his engine in order to avoid a collision, sustained a backward dislocation of the knee joint and fracture of the femur, the latter being treated by plaster of Paris without the application of any extension. He has now entirely recovered, the slight limp in his walk being due to the anchylosis in the knee joint resulting from the dislocation, the accident having happened slightly over six weeks ago. The liquid glass, as suggested by Dr. Grant, he did not think would be applicable in a hot climate, and he did not consider that the patient should, under any circumstances, be allowed to walk around. The fragments of the bone should be held in position by an assistant during the application of the plaster.

DR. MILES F. PORTER, Fort Wayne, Ind., read a paper entitled

THE CLOSURE OF WOUNDS,

in which he stated that he believed adhesive plaster to be the best substitute for stitches, and recommended its employment for operations about the face in order to avoid scars, particularly in hare-lip operations.

DR. JOHN L. SUMMERS, JR., Omaha, Neb., thought that adhesive plaster answered the purpose admirably for superficial wounds, but for deep wounds, and especially in abdominal surgery, he felt that sutures should be employed in addition to the plaster.

DR. ANDREW WADE MORTON recommended the use of this method for the closure of superficial wounds, believing it to be superior to suturing, as in this manner one would avoid pressure and the consequent tissue necrosis, but if applied in deep wounds, he believed it would simply close the outside and leave dead spaces, and this would be particularly true if employed in abdominal wounds.

DR. MILES F. PORTER stated that he did not recommend the use of adhesive plaster to replace the use of sutures in abdominal surgery, nor that it could be used in any other operation where tension existed. In regard to the moisture that might occur beneath the plaster, he felt that that would be absorbed by the skin without doing any injury. In order to avoid the difficulty in taking off the strips of plaster, he recommended that about a quarter of an inch be turned up on each end of the strip at the time of its application, thus enabling you to catch hold of it to pull it off.

DR. T. C. WITHERSPOON, St. Louis, Mo., read a paper entitled

OPERATIVE TREATMENT OF EXOPHTHALMIC GOITER,

in which he reported nine cases, in three of which he had done the operation under chloroform, the remaining six being done under a local anesthetic, and stated that he believed a $\frac{1}{10}$ to a $\frac{1}{8}\%$ solution of eucaine to be the best for

that purpose, and there should also be infiltration of the tissues below the skin. He recommended that the incision be made parallel to the sternocleido-mastoid muscle, the arteries being ligated as suggested by Wolfe and Kocher. The injection method was condemned and the time for operation must be derived from the history of the case.

DR. ALFRED E. GRANT, Denver, emphasized the importance of as speedy work as possible in these operations. He recommended that the incision be made through the skin, the arteries ligated and the capsule opened. Hemorrhage is exceedingly dangerous in these patients, owing to their usual weakened condition.

DR. EMMET RIXFORD, San Francisco, Cal., divided the condition into two classes, primary and secondary, the latter being that stage in which the symptoms supervene in the presence of an existing goiter, and the prognosis is much better in this latter class of cases. The chief danger is from the anesthetic, and local infiltration is better than general anesthesia, the sight of the instrument, etc., being kept from the patient by a cloth around the neck supported by weights. The transverse incision is to be preferred where the tumor is not too large, as the cosmetic effect is much better.

DR. J. SHELTON HORSLEY referred to the doubtful etiology of the condition, and expressed a doubt as to whether the excess of thyroid secretion was the result or the cause of the exophthalmic goiter; the treatment, if the first theory is correct, would vary materially from what it would if the last is the correct one. He reported a case in which he had done the unilateral Venesco operation, followed by marked improvement. He advanced the theory that possibly the good results produced by operation might be owing to the fact that any interference with nerves in the neck would give temporary relief similar to that observed in some cases of epilepsy.

DR. T. C. WITHERSPOON, in closing, laid particular emphasis on the importance of ligation of the arteries and the employment of a local anesthetic.

DR. F. G. CONNELL, Leadville, Colo., read a paper entitled

SUBCUTANEOUS INJECTIONS OF PARAFFIN FOR DEFORMITIES OF THE NOSE,

in which he stated that the method was chiefly of value for the treatment of saddleback noses. He gave a *résumé* of the literature on the subject, and recommended that the injections be of small amounts at different intervals rather than a large amount at one time.

DR. ANDREW WADE MORTON, California, stated that he had used this method in twenty-five cases during the past three years, bringing the melting-point up to 109° by the use of sperm oil, it having been proven that it is necessary to have the paraffin above the temperature of the blood or it will not support the deformity.

DR. WILLIAM J. MAYO, Rochester, Minn., stated that the three principal methods for the remedy of saddleback noses had been: (1) Flap carrying; (2) celluloid bridge, which after a time is liable to produce tissue necrosis, requiring its removal; and (3) paraffin injections, the last method being preferable to the others because it is more quickly done and produces a better and more permanent result.

DR. WALTER M. SPEAR, Rockland, Me., read a paper entitled

ABSCESS OF THE SPLEEN,

in which he gave a *résumé* of the literature on the subject and reported a case resulting fatally. If the diagnosis is made early and splenectomy performed, the prognosis is fairly good.

DR. E. J. MELLISH, El Paso, Tex., read a paper entitled

ANESTHESIA,

in which he stated: (1) That no anesthetic could be employed exclusively in all cases; (2) the best technique of preparation and administration and general management should be carried out; (3) it should be administered by a successful anesthetizer. He divided the cases into three classes: (1) Cases in which the indications for local anesthetic are absolute; (2) cases in which the indications for general anesthetic are absolute; (3) doubtful cases, in which a general anesthetic should be employed. The mere fact that an operation can be done under local anesthesia, he felt, is not sufficient to justify its employment.

DR. A. J. OSCHNER, Chicago, believed that with the conditions as they exist at present, — that is, anesthetics being administered by incompetent anesthetists,— less fatalities would occur from the use of ether, and if any anesthetic causes trouble during any operation it should not be employed with that particular patient. A feeling of confidence in the anesthetist on the part of the patient is of great value, and if the patient succumbs during chloroform anesthesia, the effort should be made to expel all the chloroform from the lungs possible, before beginning artificial inspiration. Free purgation prior to the administration of the anesthetic and attention to cardiac and renal conditions was recommended.

DR. WILLIAM J. MAYO, Rochester, Minn., recommended the use of the Souchon anesthetizer for operations on the mouth and throat.

DR. JOHN E. SUMMERS, JR., Omaha, Neb., called attention to the temperature curve occurring as an after-effect of the anesthesia. In emergency cases he recommended that the stomach should always be washed out prior to administering the anesthetic, and reported a case in which chloroform had been administered without this precaution, and during the vomiting which occurred when the patient was recovering from the anesthesia, a piece of potato was forced into the windpipe, and although the trachea was opened, death from asphyxiation occurred.

DR. E. J. MELLISH, in closing, felt that there was more danger in the employment of chloroform than of ether under any circumstances. The

chloroform, being heavy, is also eliminated but slowly from the lungs, and the patient will be more or less poisoned thereby for some time.

The following officers of the section were elected for the ensuing year: Chairman, DR. CHARLES A. POWERS, Denver, Col.; Secretary, DR. E. WYLLES ANDREWS, Chicago.

Recent Literature.

The Diseases of Warm Countries, a Handbook for Medical Men. By DR. B. SCHEUBE, State Physician and Sanitary Adviser, Greiz; late Professor at the Medical School in Kioto (Japan). Translated from the German by PAULINE FALCKE, with Addenda on Yellow Fever by JAMES CANTLIE, M.B., F.R.C.S., and on Malaria by C. W. DANIELS, M.B., M.R.C.S. Edited by JAMES CANTLIE, M.A., M.B., F.R.C.S., D.P.H., Lecturer of the London School of Tropical Medicine; Surgeon Seamen's Hospital Society, Albert Dock Hospital; Lecturer Applied Anatomy Charing Cross Hospital Medical School, London; Consulting Surgeon Alice Memorial Hospital, Hong Kong. With all the original colored maps, charts, illustrations, etc., together with many additional plates, from the *Journal of Tropical Medicine*. Second revised edition. Philadelphia: P. Blakiston's Son & Co. 1903.

This volume of 594 pages is a translation by Pauline Falcke of the work of Dr. B. Scheube, and therefore appears for the first time in English. It is edited by James Cantlie, M.A., M.B., Lecturer in the London School of Tropical Medicine. The last few years have practically developed a new branch of medicine in the various diseases of the tropics and their relationship to affections common in temperate climates. The volume before us is an admirable, scientific, exhaustive presentation of these various diseases, amply illustrated and accompanied by excellent bibliographies, an attribute frequently missed in our modern medical books. The affections discussed include general infectious diseases, among which plague, yellow fever, beri-beri, leprosy, yaws and other less well-known affections are considered. Among diseases caused by intoxication, pellagra, lathyrism and snake venom poisoning find a place. A very considerable part of the volume is taken up with diseases caused by animal parasites and cutaneous and local diseases, together with certain organic affections, among which is included the so-called sleeping sickness. In all about forty-five different affections are discussed, all apparently in much detail. Although in some respects the subject matter seems distinct from our everyday practice, it is certainly true that the complete education of the modern physician demands increasingly a knowledge of the diseases endemic in tropical countries. It is, therefore, a source of congratulation that this most excellent work has been translated into English, thereby rendering it available for a larger number of readers. The binding and typography is in the usual form of the publishers, and the full-page illustrations are, for the most part, instructive and well executed.

A Textbook of Legal Medicine and Toxicology. Edited by FREDERICK PETERSON, M.D., Chief of Clinic, Nervous Department of the College of Physicians and Surgeons, New York; and WALTER S. HAINES, M.D., Professor of Chemistry, Pharmacy and Toxicology, Rush Medical College, in affiliation with the University of Chicago. Two imperial octavo volumes of about 750 pages each, fully illustrated. Philadelphia, New York and London: W. B. Saunders & Co. 1903.

Dr. Frederick Peterson of New York and Dr. Walter S. Haines of Chicago act as sponsors for this new and somewhat exhaustive treatise on legal medicine and toxicology. The first volume, which alone has reached us, is comprised in 730 pages, including an index, and has as its contributors sixteen well-known names in the medical profession of this country, among which we observe Bailey, Da Costa, Eskridge, Ewing, Hammond, Hektoen, Jelliffe, Langdon and Peterson.

The object of the work is to provide both the medical and the legal professions with a comprehensive survey of forensic medicine and toxicology, a task which the editors believe has not been done in any recent book in English. The first volume is devoted wholly to legal medicine, in which particular attention is paid to laboratory investigation. The second volume it is designed to devote in part to the allied subject of toxicology.

The usual subjects of legal importance are treated in this first volume. The increasingly important matter of railroad injuries is discussed by two writers. The medical jurisprudence of life and of accident insurance is given a somewhat prominent position. Peterson writes upon the subject with which he is known to be particularly familiar, the stigmata of degeneration; insanity in general is from the pen of the late Dr. Eskridge. As in all volumes of multiple authorship, the value of the individual articles must depend upon the special fitness of their writers. Evidently excellent judgment has been used in this respect, and we shall therefore expect when this work is completed that it will stand as an expression of the best and most modern opinion upon the various matters of medico-legal interest, which with our increasingly complex civilization are of necessity absorbing more and more attention.

The volume is illustrated in part by colored reproductions, which do not to our mind convey a more definite impression of the lesions under consideration than would carefully prepared photographs in one color. The difficulty of successfully reproducing colors as they appear under pathological conditions is exemplified by these illustrations.

THE BOSTON

Medical and Surgical Journal

THURSDAY, SEPTEMBER 3, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

SANITARY ADMINISTRATION IN PENNSYLVANIA.

THE State Board of Health of Pennsylvania was established in 1885, largely as a result of the serious epidemic of typhoid fever which had occurred at Plymouth in that state in a previous year, and now, in the seventeenth annual report of the Board, Prof. W. H. Allen, in an admirable address, takes occasion to present many facts which give to his paper much more than local interest. With an unsparing hand he shows up the defects of sanitary administration in that state — defects which are plainly due, not to the inherent makeup of the board, but to the want of intelligent appreciation of its work on the part of the people. Similar defects may be found in almost any state in the Union, since when questions relating to the protection of property and the saving of human life are concerned, greater interest is manifested in and larger sums are provided for the former than for the latter. For the destruction of gypsy moths in a few limited localities a sum was appropriated three times as great as was ever granted to the State Board of Health of Massachusetts for the prosecution of its life-saving work in any year, and five times as great as the emergency fund provided for the prevention of the introduction and spread of Asiatic cholera in 1884. The small appropriation needed for preparing the material necessary for saving several thousand lives from death by diphtheria was opposed far more vigorously than the appropriation of a sum one hundred times as great for the making of state highways.

Professor Allen's address affords abundant food for thought not only to the legislature of Pennsylvania but also to every one who is interested in the public health. He introduces the subject by an excellent *résumé* of the evolution of sanitation from the earliest times, wherein, comparing the present with the past, he says:

> The general death-rate has fallen from twenty-eight or thirty per thousand to eighteen or twenty. This saving exceeds a hundredfold the expense of administering precautionary measures. Many attempts to estimate this economic saving have been made, but there is no way of estimating the economic gain. What humanity gains by increased vitality, fresh blood, bounding pulse and clear eye cannot be set in figures.
>
> The most sceptical, even more doubtful, perhaps, than the unprogressive mine operator or factory owner, is the inferior physician. Unfortunately he too often believes that the state is arrogating to itself the functions of his profession when it prescribes regulations for infectious diseases. He frequently resents the dictational attitude of the state when it limits the sphere of his own activity or imposes upon him uncompensated duties. The medical profession as a whole, however, has outgrown this dependence upon transmissible diseases and recognizes that its prosperity increases with every increase in the average standard of living. It is the man in the ten-room house rather than he in the one room who supports the physicians in luxury. It is the healthy man, the healthy family and the healthy community that pay large doctor's bills. Society to-day prefers to regard the family physician as an educator rather than a physician, one who prepares patients to avoid disease rather than one who does a general repairing business. It is probably true that medical curricula have not as yet adequately emphasized the socialization of the physician's skill; but fortunately, an advanced public sentiment, aided by teachers of social sciences and voluntary educational and scientific organizations, is effectually supplementing the medical curriculum and preparing the young physician to lead in sanitary reforms.

In the chapter on "Sanitation in Pennsylvania" the author treats of the sanitary condition of the state as it existed at the date of organization of the State Board of Health, and although many laws had been enacted providing for the sanitary protection of the people, but little provision had been made for their enforcement, the entire sum provided for the work of the State Board of Health in a state of six million inhabitants up to the present time being only $6,000 per year, or only one-tenth as much as is given for similar work in Massachusetts, a state having a population one-half as large.

When the State Board of Health was established, the only statute guaranteeing the protection of rivers against pollution was enacted to ensure the preservation of the fisheries. The legislature had also enacted laws with severe penalties to prevent the exposing of poisoned meat with the intent that it should be taken by horses, cattle or other domestic animals or fowl.

In the words of the writer, "From protection to dogs and chickens and fish to protection of human beings seems an easy step, yet after thirty years it seems as distant as ever." The effect of this gross and habitual neglect is shown in the high death-rate from typhoid fever which Philadelphia constantly suffers.

Prominence is justly given to the important subject of vital statistics:

> The object of gathering them is not to furnish material for future historians. They are to be used in shaping future history. They are facts collected with a view to improving social vitality, to raising the standard of life and to eliminating permanently those forces known to be destructive to health. Unless they are to be utilized in this way, they are of interest only to the historical grub. The state cannot afford to erect a statistical office to serve as a curiosity shop. Unless something is to be done to prevent the future recurrence of typhoid epidemics such as our cities, Pittsburg, Philadelphia, etc., have annually experienced, there is no special reason for asking the public printer to make tables which indicate the great cost of this preventable disease. Unless some one is at hand to abate the causes of transmissible diseases and to check infection at its inception, the notification of infection is of little social utility. Statistics presume efficient administration. An inefficient health officer will not care to gather statistics. If some one else furnishes him with statistics, they are as a lantern to a blind man.

Professor Allen's paper forms a distinct and valuable contribution to the literature of sanitary administration, and should be thoroughly read by every health officer who seeks the good of the community which he serves.

"THE INVALID'S EGYPT."

THE paper by Dr. F. Gordon Morrill, published in last week's issue of the JOURNAL, entitled "The Invalid's Egypt," is to be commended as a model of what that sort of paper should be both in form and substance. This is Dr. Morrill's second communication to these pages on Egypt, a previous paper having appeared in our issue for Nov. 28, 1901.

We take occasion to call attention to "The Invalid's Egypt" for several reasons: It is brief and concise, yet nothing of genuine importance to the physician who advises or to the invalid who thinks of going to Egypt is omitted; the information given is not compiled, but is drawn at first hand from intimate personal knowledge and experience, and the conclusions stated are the result of careful and revised intelligent professional observation, unbiased and unaffected by individual interests or surroundings.

We wish there were more such statements in regard to other countries frequented by large numbers of our health-seeking or travel-loving fellow-countrymen and countrywomen.

We are all called upon more or less frequently for counsel as to climates, as to the benefits to be expected from or the dangers to be guarded against in this or that country; as to the distinguishing characteristics of this or that locality and of the various periods of the twenty-four hours; as to what season of the year is best in one place and what in another; as to what clothes should be taken.

Too many invalids have gone or have been sent to distant places without an adequate or exact knowledge on their own part or on that of their medical advisers of what they were to prepare for or to encounter when reaching thei proposed destinations.

We therefore welcome on behalf of the physician and on behalf of the traveler, whether invalid or not, all such contributions as those of Dr. Morrill, to which we take very great pleasure in directing our readers' attention.

THE LATE MAJOR WALTER REED, M.D.

WE are glad to publish in another column a statement of the recent meeting held in Bar Harbor by friends of the late Major Reed to decide upon some fitting memorial for him and to attract public attention to one of the great medical benefactors of the time. A glance at the names of the men who took part in this meeting is sufficient guarantee of the wide and appreciative interest taken in Major Reed and his work by men not only of the medical profession, but others with large interests in progress of whatsoever character.

The conclusion reached by this first meeting was that an effort should be made to raise a memorial fund of at least $25,000, the income to be devoted to Dr. Reed's widow and daughter and later to be appropriated to the promotion of research in Dr. Reed's special field, or to the erection of a memorial to him in Washington. We have no doubt that this really modest appeal will meet with a hearty response not only from physicians everywhere but also from others of humanitarian feelings. Dr. Reed's services in the cause of medicine, and so in the cause of civilization at large, are hardly to be overestimated, and the least we may do in such a case is to express our appreciation by a quick and liberal response to the request which has been made by the committee having the matter in charge. We are

inclined to think that if more general public recognition could be had of the services of physicians who have made great discoveries in the realm of science or applied medicine, it would conduce to a better appreciation of the fundamentally important work which the medicine of the future has in store, and also possibly lead to a juster comprehension of the sacrifices and often true heroism of men engaged in the difficult and dangerous pursuit of knowledge as it relates to infectious disease. The public is notoriously slow to recognize merit unless it is brought to its attention in some palpably objective way. To this end it is both right and fitting that men who have rendered such service as this of Dr. Reed's should receive a commemoration which will be both enduring and impressive. We sincerely hope that the minimum amount of $25,000 may be far surpassed when the full significance of the memorial is appreciated by the public, whether lay or professional.

THE NEW MASSACHUSETTS GENERAL HOSPITAL OUT-PATIENT DEPARTMENT.

WE make mention in another column of the opening of the new out-patient department for the Massachusetts General Hospital, which has been under construction during the past two years. Although the opening of this large department of the hospital's work appears to have taken place without ceremony of any kind, we nevertheless feel that the importance of the work which this new building represents is worthy of mention from several points of view. In the first place, with the construction of a building of this size and equipment comes the recognition that the often somewhat neglected ambulatory practice of a great hospital is one of its most important functions. This is true not only from the point of view of the patient, but also from the standpoint of the development of medicine at large.

We have hardly as yet begun to develop the possibilities in the way of research and investigation which are inherent in a properly equipped out-patient department. There can be no question that with the ample facilities now at their disposal the physicians connected with this department of the hospital will gain a new inspiration for thorough, conscientious work. Such facilities as are now offered certainly bring with them an added responsibility on the part of the medical profession to avail themselves to the full of their new privileges.

We note, also, with gratification that in the planning of this new building those in authority have considered that most important function of the modern hospital — teaching. Two excellent, commodious amphitheaters are provided for the use of students, and the general arrangement of the rooms is such that teaching may be done in the various departments without interruption and therefore to good effect. We can see no reason why in this new building the needs of the patients, of the physicians and of the medical students who are later to become physicians may not be completely subserved. The effect of so imposing a structure, with so complete an equipment, cannot be other than to elevate the out-patient department, not only at this hospital but elsewhere, to the position which it should long since have taken in general hospital economy.

MEDICAL NOTES.

SMALLPOX AND TYPHOID FEVER IN PHILADELPHIA. — Typhoid fever, which is prevalent in Philadelphia, shows no tendency toward abatement. The increase in one week during the latter part of August was nearly thirty. Smallpox also still prevails in the city, with about twenty cases now under observation.

A DISCREPANCY. — *American Medicine* is authority for the statement that a male infant weighing thirteen ounces was recently admitted to the New York Post-Graduates Hospital, and that the birth of a twenty-five pound female child is announced from Lexington, Ky.

DEATH OF DR. SALAZAR. — The report has been generally circulated that Dr. Salazar, physician in charge of the American Hospital in Tampico, Mexico, has died of yellow fever, contracted during his vigorous attempt to check the spread of the disease in that place. Even after he recognized the fact that he had contracted the disease, he persisted in directing the work of the hospital.

RESIGNATION OF DR. G. A. SOPER. — It is reported that Dr. G. A. Soper, expert of the New York State Health Department in relation to the Ithaca typhoid fever epidemic, has resigned, through dissatisfaction with the dilatory policy of the local authorities.

FOURTH OF JULY CASUALTY LIST. — A special investigation of the various casualties incident

upon our last July 4 is published in the current issue of the *Journal of the American Medical Association*, and contains many facts worthy of serious thought. In the Northern and Western states 406 deaths occurred from tetanus, usually due to the toy pistol. Aside from tetanus in the celebration of the Fourth of July this year, 60 deaths were caused, 10 persons made blind, 75 persons lost one eye, 54 lost hands, arms or legs, 174 lost one or more fingers and 3,670 received other injuries, making a total of 3,983 persons injured. Adding the deaths from tetanus and from other causes, 4,449 persons are dead or injured. These figures should point a moral and teach a needed lesson.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Sept. 2, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 41, scarlatina 13, typhoid fever 33, measles 11, smallpox 0.

OPENING OF NEW OUT-PATIENT DEPARTMENT AT THE MASSACHUSETTS GENERAL HOSPITAL. — The newly constructed out-patient building at the Massachusetts General Hospital was opened, without ceremony, for the reception of patients Aug. 31. The new building is located at the foot of Fruit Street, adjoining the general hospital. It is a three-story brick structure, in the shape of an L, constructed thus for the purpose of obtaining as much light as possible. The basement is occupied by the record room and the apothecary's headquarters, with a waiting-room for those whose prescriptions can be filled without consultation with the house physician. There is also a large room equipped for x-ray work. The first floor is devoted to men. On the second floor is the women's department, connected with which is the children's section, and on the top floor are the sections devoted to the treatment of diseases of the throat, nerves and skin.

A CODFISH FAMINE IS THREATENED. — It is said that the price of cod has reached the highest point since the civil war and that at present the receipts are approximately one-fourth of the regular supply, with small prospects of improvement. It is furthermore reported that the price of cod-liver oil, which comes largely from Norwegian fishing grounds, has advanced from $22 to $160 a barrel for the raw material. The reason for the deficiency of this usually abundant fish is worthy of and no doubt will have careful investigation.

NEW YORK.

SUICIDE IN 1902. — From statistics collected by Frederick L. Hoffman of the Prudential Insurance Company in regard to suicide in the year 1902 in fifty American cities, having an aggregate population of fourteen and one-half millions, it appears that the rate was highest in Hoboken, N. J., being thirty-five per hundred thousand. In New York the rate was twenty-one.

LONDON AND NEW YORK PARKS. — On returning from a trip abroad Commissioner of Parks Wilcox recently stated, in comparing London and New York parks, that while London probably had more space in its parks, he thought the system of gymnasiums and the park attendants system of New York were superior. London had a few parks equipped with gymnasiums, he said, but none compared with the William H. Seward Park in New York and he did not believe that any five parks in the English city contained as many features as the Seward Park.

APPROPRIATION FOR BOARD OF HEALTH. — The estimate of the Board of Health for the appropriation it will require for conducting the department during the year 1904 is $1,631,500 as against $1,047,721 allowed for the present year. The estimate includes $50,000 for the construction and equipment of a new steamboat.

ITHACA WATER SUPPLY. — On Aug. 22 the Ithaca Water Company commenced pumping water from its newly completed filter station into the mains of the city of Ithaca. It will be remembered that six months ago Cornell University loaned the water company $150,000 for the building of a purification plant, and the result of the work, which has been conducted by expert engineers, has been pronounced entirely satisfactory by Dr. Soper, the representative of the State Health Department at Ithaca. It is described as follows: "The plant is built on the mechanical or rapid system of purification. The water as soon as delivered to the receiving wells is charged with a solution of sulphate of alumina, which forms a flocculent precipitate which rapidly coagulates any organic impurities in the water, combined or suspended. The water is then passed into settling basins, where 70% of its impurities are precipitated. It then passes through six filters of 3,000,000 gallons daily, capacity." At

the time of the typhoid fever epidemic at Ithaca the mayor appointed a water commission, which decided that the best method to obtain a pure supply was by the sinking of artesian wells, and accordingly a number of such wells have been driven by the city. The water company, however, after consulting the best experts on the subject, concluded that the construction of a filter plant was the only practicable way in which it could furnish its patrons with pure water. It is stated that the experts all agreed that the correct solution of the Ithaca water-supply problem was not to try for different water, but to take that which was already in use and purify it.

Miscellany.

MEMORIAL OF THE LATE MAJOR WALTER REED, M.D.

On the 15th of August a meeting was held in Bar Harbor of friends of the late Major Reed, M.D., U. S. A., to whom in a large degree is due both the discovery of the mode by which yellow fever has been spread and also the consequent suppression of that dire disease. Representative men were present from different parts of the country and letters were received from various members of committees already appointed to promote the collection of a memorial fund in grateful commemoration of Dr. Reed's services. Important suggestions were presented from President Eliot, Dr. W. W. Keen, Prof. J. W. Mallet and others. Dr. Daniel C. Gilman, chairman of a committee appointed by the American Association for the Advancement of Science, presided, and Dr. Stuart Paton acted as secretary. Among those who took part in the conference were Dr. W. H. Welch of Baltimore, Dr. Janeway of New York, Dr. Abbott of Philadelphia, Dr. Hertor of New York, Dr. Barker of Chicago, Dr. Putnam of Buffalo, Dr. Fremont Smith of Bar Harbor and Dr. Sajous of Philadelphia; and besides these medical gentlemen, Bishop Lawrence of Massachusetts and Messrs. Morris K. Jesup, President of the New York Chamber of Commerce, John S. Kennedy, President of the Presbyterian Hospital of New York and William J. Schieffelin of New York. The following conclusions were reached: That an effort should be made to raise a memorial fund of $25,000 or more, the income to be given to the widow and daughter of Dr. Reed, and after their decease the principal to be appropriated either to the promotion of researches in Dr. Reed's special field, or to the erection of a memorial in his honor at Washington.

Arrangements were made for the publication of circulars explaining this movement and asking co-operation not only from the medical profession but from all liberally disposed individuals who appreciate the value of Dr. Reed's services to mankind.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUG. 22, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Disease.	Typhoid fever.

Deaths reported, 3,182; under five years of age, 1,236; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,181, acute lung diseases 193, consumption 351, scarlet fever 15, whooping cough 18, cerebrospinal meningitis 11, smallpox 12, erysipelas 6, measles 10, typhoid fever 70, diarrheal diseases 625, diphtheria and croup 59.

From whooping cough, New York 10, Chicago 1, Philadelphia 3, Pittsburg 1, Fall River 1, Fitchburg 2. From erysipelas, New York 2, Philadelphia 1, Pittsburg 1, Providence 2. From smallpox, Chicago 2, Philadelphia 2, Pittsburg 8. From scarlet fever, New York 4, Chicago 2, Philadelphia 3, Baltimore 1, Providence 1, Boston 1, New Bedford 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Aug. 8 the death-rate was 14.3. Deaths reported, 4,139; acute diseases of the respiratory organs (London) 107, whooping cough 61, diphtheria 44, measles 57, smallpox 8, scarlet fever 38.

The death-rate ranged from 5.1 in Burton-on-Trent to 26.6 in Bootle. London 15.0, West Ham 11.1, Brighton 10.0, Portsmouth 9.9, Southampton 8.5, Plymouth 13.5, Bristol 13.2, Birmingham 14.3, Leicester 11.1, Nottingham 15.1, Bolton 17.7, Manchester 17.5, Salford 17.3, Bradford 15.5, Leeds 15.8, Hull 16.3, Newcastle-on-Tyne 20.4, Cardiff 9.7, Rhondda 1.39, Liverpool 18.0, Hornsey 5.3, Warrington 19.6.

METEOROLOGICAL RECORD.

For the week ending Aug. 22, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING AUG. 20, 1903.

BANKS, C. E., surgeon. Three days' leave of absence from Aug. 8, 1903, under paragraph 189 of the regulations.

CARMICHAEL, D. A., surgeon. Bureau order of Aug. 10, 1903, directing Surgeon Carmichael to report to Director of Laboratory for special instructions, amended so that he shall report at the Laboratory for temporary duty. Aug. 17, 1903.

PERRY, J. C., passed assistant surgeon. Relieved from temporary duty in the Bureau, and directed to report to the Director of the Laboratory for duty. Aug. 15, 1903.

ROSENAU, M. J., passed assistant surgeon. Granted leave of absence for seven days from Aug. 19. Aug. 18, 1903.

NYDEGGER, J. A., passed assistant surgeon. Granted leave of absence for one month from Aug. 13, 1903, on account of sickness. Aug. 20, 1903.

WICKES, H. W., passed assistant surgeon. Leave of absence for one day granted by Bureau telegram of Aug. 13, 1903, revoked. Aug. 20, 1903.

PARKER, H. B., passed assistant surgeon. Relieved from special temporary duty at Vera Cruz, Mexico, to date from July 22. Aug. 17, 1903. Granted leave of absence for seven days from Aug. 19. Aug. 18, 1903.

MCCLINTIC, T. B., assistant surgeon. To report to Director of the Laboratory for duty, to take effect Aug. 1, 1903. Aug. 17, 1903.

WILLE, C. W., assistant surgeon. Relieved from duty at the Laboratory, to take effect Aug. 3. Aug. 17, 1903. Detailed as inspector of unserviceable property at Baltimore, Md. Aug. 18, 1903.

DELGADO, J. M., acting assistant surgeon. Granted extension of leave of absence for seven days from Aug. 12. Aug. 17, 1903.

FOSTER, J. P. C., acting assistant surgeon. Granted leave of absence for seven days from Aug. 19. Aug. 19, 1903.

FRISSELL, C. M., acting assistant surgeon. Department letter of Aug. 6, 1903, granting Acting Assistant Surgeon Frissell leave of absence from Aug. 6 to 18, amended to read from Aug. 10 to 25. Aug. 17, 1903.

SCHUG, F. J., acting assistant surgeon. Granted leave of absence for ten days from Aug. 15. Aug. 17, 1903.

SPOHN, A. E., acting assistant surgeon. Granted leave of absence from July 26 for thirty days. Aug. 17, 1903.

APPOINTMENTS.

Jamin H. Hamilton appointed acting assistant surgeon for duty at Richford, Vt. Aug. 5, 1903.

Stacy D. Williamson appointed acting assistant surgeon for duty at Malone, N. Y. Aug. 14, 1903.

PROMOTIONS.

Assistant Surgeon L. D. Fricks commissioned (recess) as passed assistant surgeon, to rank as such from Aug. 2, 1903.

Assistant Surgeon V. G. Heiser commissioned (recess) as passed assistant surgeon, to rank as such from Aug. 3, 1903.

Assistant Surgeon M. J. White commissioned (recess) as passed assistant surgeon, to rank as such from Aug. 4, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING AUG. 29, 1903.

E. M. BROWN, assistant surgeon. Detached from the Naval Hospital, Newport, R. I., and ordered to the "New York."

M. S. ELLIOTT, surgeon. Detached from the "New York" and ordered home to wait orders.

N. H. DRAKE, surgeon. Detached from the "New York" and ordered to the "Maine."

D. O. LEWIS, surgeon. Ordered to the "New York" as fleet surgeon of the Pacific Squadron.

H. C. CURL, passed assistant surgeon. Detached from the Naval Hospital, Mare Island, Cal., and ordered to the "New York."

W. R. DUBOSE, surgeon. Detached from the "Maine" and ordered to duty in the Bureau of Medicine and Surgery.

J. F. MURPHY, surgeon. Detached from the "Monocacy" and ordered to the "Wisconsin."

J. C. THOMPSON, assistant surgeon. Detached from the "Chesapeake" and ordered to the Naval Academy.

RECENT DEATHS.

ALLEN R. THOMPSON, M.D., a prominent physician of Troy, N. Y., died at Asbury Park, N. J., on Aug. 22, at the age of forty-five.

WILLIAM S. PLAYFAIR, M.D., of London, one of the most distinguished gynecologists and obstetricians of England, has recently died at the age of sixty-seven. Beyond his very large and successful practice, he was the author of two books on obstetrics, one of which became popular as a textbook and was reprinted in the United States.

CHARLES F. HILDRETH, M.D., died at Manchester, N. H., Aug. 18, at the age of seventy-one. He was graduated from the Harvard Medical School; began practice in Concord, N. H., and was for several years surgeon at the State Prison. During the civil war he served as assistant surgeon in the navy and also as surgeon in the 40th Massachusetts Regiment. At the conclusion of the war he began practice again in Concord, and later removed to Manchester, where he was at the time of his death.

BOOKS AND PAMPHLETS RECEIVED.

Manual of the Diseases of the Eye, for Students and General Practitioners. By Charles H. May, M.D. Third Edition. Illustrated. William Wood & Co. New York, 1903.

Inefficiency of Ferrous Sulphate as an Antiseptic and Germicide. By Allan J. McLaughlan. U. S. Public Health and Marine Hospital Service. Bulletin No. 15. Washington, 1903.

Mundpflege bei Quecksilberkuren und einigen Mundaffektionen. von Julius Mueller, M.D. Berlin, 1903.

Consideration of the Medico-Legal Aspects of Aphasia. By Charles H. Hughes, M.D. St. Louis, 1903.

Some Practical Suggestions on Tropical Hygiene. By Maj. Henry P. Birmingham, Surgeon, U. S. A. Reprint. 1903.

Artificial Parthenogenesis in Molluscs. By Jaques Loeb. University of California Publications, Aug. 3, 1903.

Secondary Eruptions in Smallpox. By Jay F. Schamberg, A.B., M.D., of Philadelphia. Reprint. 1903.

A Thesaurus of Medical Words and Phrases. By Wilfred M. Barton, M.D., and Walter A. Wells, M.D. W. B. Saunders & Co., Philadelphia, New York, London. 1903.

Verhandlungen des Vereins für innere Medizin in Berlin. Herausgegeben von dem Vorstande des Vereins. Jahrgang XXII, 1902–1903. Sonderabdruck aus der "Deutschen Medizinischen Wochenschrift." Jahrgang 1902 und 1903. Berlin, 1903.

Radium and Other Radio-active Substances; Polonium, Actinium and Thorium, with a Consideration of Phosphorescent and Fluorescent Substances, the Properties and Applications of Selenium and the Treatment of Disease by the Ultra-violet Light. By William J. Hammer. Illustrated. New York: D. Van Nostrand Co. 1903.

Modern Bullet Wounds and Modern Treatment, with Special Regard to Long Bones and Joints, Field Appliances and First Aid. Part of the Alexander Essay for 1903. By Major F. Smith, D.S.O. Philadelphia: P. Blakiston's Son & Co. 1903.

Transactions of the Seventieth Annual Session of the Tennessee State Medical Association. Nashville. 1903.

The Practical Medicine Series of Year Books, comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. VIII. Chicago: The Year Book Publishers. July, 1903.

Twenty-second Annual Report of the State Department of Health of New York, for the Year Ending December 31, 1902. With maps. Albany, 1902.

CANCER OF THE INTESTINE, ETC.; ITS SURGICAL ASPECT, WITH REPORT OF CASES.[1]

BY HOMER GAGE, M.D., WORCESTER, MASS.

THE danger of septic infection was one of the most important if not the controlling factor in limiting the field within which surgical operations could be properly undertaken a generation ago. Its removal by the development of an aseptic technique marks the beginning of a new surgery, one of whose first impulses seems to have been to see how much mutilation and interference nature will permit. Life is found to be quite livable without many of the organs that had hitherto been supposed to be essential to its existence.

But now that the possibility of these radical excisions and resections is established, must come the second stage in the new surgery, namely, a careful study of the remote as well as the immediate results of these new operations.

It seems quite certain that we shall discover that much that is possible is attended with very grave dangers to life, and is followed by an impairment of comfort and health that makes the life that is left hardly worth living. Already strong protests are being made by our medical brothers against many of the more radical operations — protests that must be heard and if possible answered, for, after all, our purpose must be, not to see what surgical feats can be successfully accomplished, but how they can be made to contribute to the prolongation of life and the relief of suffering.

One of the most notable protests that has been made recently was contained in the anniversary discourse before the New York Academy of Medicine, delivered Dec. 5, 1901, by Dr. Reginald H. Fitz of Boston.

It is an exceedingly temperate and judicial review of the ultimate results of surgical interference with diseased conditions that had hitherto been regarded as incurable. Much of it is naturally taken up with a consideration of the surgery of internal cancer, and it is to one feature of this that I wish to call your attention for a few moments.

In the records of the Massachusetts General Hospital for the ten years from 1890 to 1900 he found "ten cases of intestinal resection for cancer, of which eight died within a month after the operation; the ninth patient was found to have a girdling ulcer without gross evidence of malignant disease, although from microscopical examination regarded as an adeno-carcinoma. He was at work as janitor and enjoying fair health two and a half years after operation. The tenth patient was not heard from. Of the five cases of intestinal anastomosis (for cancer) two died within the fortnight following operation; one lived six months and two have not been heard from." "Of the seventy-seven cases of cancer of the alimentary canal two, or only 3%, were living at the end of three years after the operation."

If we consider the question of relief of suffering in those whose history subsequent to the operation could be learned, the result is equally disappointing. I have thought it would be worth while, therefore, to look very briefly at the results which have been obtained by others in the surgical treatment of intestinal cancer, and to add my own small, but to me, significant experience.

In the first place, one finds it quite unsatisfactory to depend overmuch upon a general compilation of reported cases. The immediate results are so much better than the full reports from the more important clinics that one feels at once that the tendency to report individual successes makes the general table relatively unreliable as a true index of the general mortality, and, further, most of the cases are reported too early to give any assurance of the success or failure of the operation. Lardennois collected 241 cases with 24 deaths, a mortality of 34.8%, and Bovis 171 cases, with a mortality of 31.5%. Contrast this with the combined experience of such operators as Krönlein, Korte, Czerny, Billroth-Salzer and König, whose 58 cases resulted in 28 deaths, a mortality of 48.4%; of these Korte's record of 19 cases with 7 deaths, or 36.8% is the best — all of the others having a mortality of 50% or over. At St. Thomas' Hospital between 1888 and 1897, there were 12 resections with 7 deaths, and Von Bramanns in 1897 reported 14 cases with 6 deaths.

According to Korte, the cecum is the most favorable locality for operative interference, he having resected for carcinoma five times and sarcoma once, with no deaths. This view is further supported by McEwen, who reports 5 cases with one death, and by Goullioud, who had 6 enterectomies for cancer of the cecum, with but one death; Krönlein, however, had 6 cases with 3 deaths. It follows that the general mortality in intestinal resection for malignant disease is still very high,— almost 50%,— except possibly in the region of the ileo-cecal valve. So much for the immediate, now let us look for a moment at the later results.

Of Korte's 12 successful cases, 5 were well from 3 to 8½ years after operation, 3 of his cases of resection of cecum being alive 8½, 6¼ years respectively. Two of McEwen's cases were alive more and 2 less than 3 years after operation. One of Goullioud's patients was alive 3 years, the others less than 1 year, while Krönlein had 5 cases in which there had been no recurrence at the end of from 5 months to 14 years. Of Von Bramanns' cases, 4 had remained well for more than 3 years and 3 for less.

Taking the experience of these operators, all of whose reports seem very complete, there were 56 cases, of which 13, or 23 %, had survived the 3-year limit without any evidence of returning disease. These figures are, it seems to me, distinctly encouraging, and do much to overcome

[1] Read before The Massachusetts Medical Society, June 9, 1903.

the prejudice naturally evoked by the very unfavorable statistics quoted by Dr. Fitz.

It must be remembered that the field is comparatively new, that the diagnosis is not usually made until the disease is pretty well advanced and that a considerable accumulation of experience must be made to furnish a basis for selection of cases suitable for operation. In view of the experiences already quoted, it seems reasonable to assume that when the growth has not extended beyond its original seat, and can be removed with a liberal margin of uninvaded tissue, although the immediate mortality will be large, a period of immunity from recurrences can be fairly expected in a proportion of cases that will compare favorably with the results obtained from the removal of cancer in other organs.

My own experience consists of but four cases:

CASE I. Cancer of the small intestine; acute intestinal obstruction, without previous symptoms. Operation on tenth day. Death from shock. Male, twenty-three years old, seen in consultation with Dr. W. M. Pearson of Ware. Had typhoid fever seven years ago, and has been troubled with constipation and occasional attacks of indigestion for two or three years, a very hearty eater, strong and active up to the advent of his last illness. On March 12 he ate a large quantity of cheese, from one-half to a pound, and on the following day was suddenly seized with pain in his stomach and vomiting. The pain subsided, but a continuance of the vomiting led him to consult Dr. Pearson on the 15th. In spite of a good variety of cathartics and enemata, no movement of the bowels could be secured, and the vomiting persisted. There was no distention and but little pain. Temperature had not been above 99, and until the evening of the 24th pulse had been of good quality and about 100.

On the evening of the 24th he showed signs of exhaustion, the vomiting became stercoraceous, and the pulse rose to 130. I saw him at 2 A.M. on the 25th; he was conscious, with a pinched, anxious expression, tongue moist, extremities somewhat cold and was very restless. The abdomen was not distended, but was somewhat tender, especially to left of median line below level of umbilicus, where there was a distinct increase of muscular resistance, and where under ether a definite tumor could be easily made out.

On opening the abdomen the intestines were empty and collapsed; there was a small amount of turbid serum present and some very recent easily separated adhesion. The lump on the left side was delivered through the incision and found to be contained within the lumen of the gut, which on its surface showed simply signs of fresh peritonitis. The portion containing the lump was partially intussuscepted into the intestine beyond. This part was resected, and the two ends united by a double row of sutures. The patient's condition was very unsatisfactory from the beginning, and he died about three hours after the operation. The specimen was examined by Dr. F. H. Baker, who reported "that it consisted of about four inches of the small intestine, probably the lower part of jejunum. On opening, it is seen to be nearly occluded by a firm, irregular, lobulated polypoid growth, with a thick base and without ulcerations. The growth measures one and a half inches in width. No growth is apparent on the exterior surface of the bowel, but there was some contraction about the base of the tumor. Microscopical sections show it to be made up of an exuberant growth of glandlike structures, irregularly lined with columnar epithelium. Many of the glands are somewhat necrotic. Between the glands there is a coarse fibrous stroma.

"The diagnosis is adeno-carcinoma of the small intestine."

I have given the history of this case at some length because cancer in this locality is exceeding rare, and because its existence was so entirely unexpected. There was absolutely nothing in the young man's history that would lead any one to suspect the real condition. It illustrates afresh the value of operating early in all cases of intestinal obstruction, and the possibility, in some cases at least, of finding a cancerous growth that has not invaded the walls of the bowels and has no palpable secondary glands. A more perfect case for complete and thorough removal of cancer in any part of the body could not be desired. It is a strong incentive to a careful study of the conditions which should lead to earlier recognition and operation.

CASE II. Cancer of cecum; symptoms of chronic appendicitis; resection; alive and well now, two years and eight months after operation. Miss N., thirty years old, a seamstress, had always had a spot in right side that was tender; supposed she had inherited a gastric trouble from her mother. For more than ten years had been awakened in the night by attacks of colicky pain in abdomen, and for four years these had been growing more and more frequent. There was always severe pain in the right side, and the attacks of colic would occur perhaps twice in a week, and then not for six weeks; would sometimes last several hours, and were controlled only by morphine. For two years she had noticed that the gas would collect and form a bunch in the right iliac region. She had been very constipated, but the movements had been normal in appearance. During the last year she had lost flesh, and found it difficult to keep on with her work. She was referred to me as a case of chronic appendicitis. There was marked tenderness with a distinct mass in the cecal region, and I acquiesced in the diagnosis.

I operated Sept. 20, 1900, and found the cecum converted into a hard mass; appendix not involved, normal in appearance, and the lower end of the ileum very much dilated. There were no enlarged mesenteric glands. The cecum was movable and not adherent to any of the adja-

cent structures. I excised it with a portion of the ileum as well as of the ascending colon. So much enlarged was the caliber of the small intestine that an end-to-end suture with the colon was easily effected. Her recovery was uninterrupted, and except for a small ventral hernia, which is easily controlled, she has been in better health than ever, with no sign of recurrence.

Dr. Baker reports "that the specimen consists of the last two inches of the ileum and the first five inches of the cecum. There is no evidence of the growth on the outside of the intestine, but involving the ileo-cecal valve there is felt a hard, contracting, encircling mass. On opening the lumen, the ileo-cecal valve is contracted so that its aperture is about the size of an ordinary lead pencil. Numerous small papillary growths project into the lumen about the ileo-cecal valve, and several small isolated ones are seen springing from the mucosa of the cecum as far up as one and a half inches from the valve. Sections show the intestinal wall to be about four times its normal thickness, and to be infiltrated with an adenomatous growth. The diagnosis is adeno-carcinoma."

The result in this case certainly justified the interference, and is worth making several unsuccessful efforts to attain. If we could obtain as complete immunity in even 20% of our cases, it would be as favorable a showing as we can get in some of the better established and less opposed operations for cancer, in some of the more superficial and easily accessible parts of the body.

CASE III. Cancer of hepatic flexure; chronic intestinal obstruction; resection with artificial anus; subsequent closure; death from recurrence.

The patient was a male, fifty-two years old, who had for years been a pretty constant sufferer from intestinal indigestion and constipation. In 1898 he went to Cuba as a captain in the regular army; had while there a severe attack of dysentery, and was invalided home. For a time he seemed to be much better and stronger than he had been for many years, but during the winter of 1901–2 his old trouble returned, and he was evidently losing both flesh and strength.

About March 1, 1902, he had a severe attack of abdominal distress, with vomiting and obstinate constipation. Flatus passed freely, and there were some small but unsatisfactory movements. During the next twelve days his condition became worse; there was severe abdominal distention, but no local pain or tenderness. He could retain very little nourishment, and as the obstruction seemed to be growing more complete, in consultation with his attending physicians, Drs. Wood and Baker of Worcester, I advised his removal to the hospital for exploratory incision.

This was done on March 13, and I found the obstruction to be caused by an annular constriction in the neighborhood of the hepatic flexure. A hard infiltrating and contracting mass involved the whole circumference of the bowel, which was intimately adherent to the abdominal wall. There were several enlarged glands to be felt in the adjacent mesentery. I succeeded in freeing the mass and excising it with enough of the mesentery to include the glands which I had felt. The patient's condition was such that I did not feel justified in attempting a careful suture, and had to be satisfied with an artificial anus at that point. He rallied well from the operation, was able to take and retain his nourishment, and at the end of a week was removed to his home.

Here he gained rapidly in flesh and strength, and was able to be up and walk about the house. On the 25th of April, six weeks after the first operation, I attempted to close the fistula and found the disease was already returning in the mesentery and adjacent parts. Symptoms of obstruction quickly supervened, and he died on the 25th of May.

Dr. Baker reported "that the specimen consisted of about five inches of the ascending colon near the hepatic flexure. Occupying about two inches of the middle was a firm, nodular, encircling, contracting growth, with broken adhesions over its external surface. This growth in the interior of the intestine presents a rough polypoid surface with several small areas of ulceration. The lumen of the gut was reduced to a little less than one-half inch. Sections showed the mucosa and submucosa in places to be nearly destroyed, and the growth to be made up of an irregular-shaped glandlike tissue, with the glands lined with columnar epithelioma. Some sections showed marked necrosis. The interglandular stroma was made up of coarse fibrous tissue. Adeno-carcinoma of large intestine."

The operation in this case is fairly open to the criticism made by Dr. Fitz upon surgical interference with intestinal cancer in general. If it was reasonable to open the abdomen and to make sure that the obstruction was not something that could be easily and safely relieved, a matter perhaps it should have been possible to decide without, in view of the extent of the disease and the improbability of being able thoroughly to remove it, I think the interference should have stopped there. I shall certainly never again attempt or advise removal under similar conditions.

CASE IV is one which I reported in the BOSTON MEDICAL AND SURGICAL JOURNAL for Dec. 19, 1901. It was that of a man seventy-five years old, who was operated on by Dr. McBurney of New York for acute intestinal obstruction. Six inches of the lower half of the sigmoid flexure was resected for carcinoma. Five years later I operated for a second obstruction caused by internal strangulation, and found no evidence of recurrent disease. He is alive and well now, seven years after the removal of the cancer, and in his eighty-second year.

Clinically these cases illustrate three different ways in which the presence of a malignant growth in the intestinal canal may manifest itself. In two, acute intestinal obstruction was the first indication of the existence of any serious trouble. There had been absolutely nothing in either

case to suggest the possibility of organic disease, and as we review the histories of intestinal cancer in the reported operations, one is surprised to find how often its development proceeds wholly unsuspected.

The diagnosis in this class, therefore, cannot be made until the abdomen has been opened, and there can be no question as to the propriety of the operation. When, as in Case II, the accompanying symptoms are such as to suggest a chronic appendicitis, — and the frequency with which cancer is found in the cecal region makes this class relatively a large one, — the desirability of surgical interference is equally clear.

The existence of the more serious lesions can seldom be made out beforehand, and fortunately the early appearance of the symptoms can lead to an early discovery of the growth by a surgical incision, and to its early removal while yet confined to its original seat, when all the conditions for success are most favorable. This explains, I think, in no small measure, the comparative low mortality and long immunity from recurrence observed in cases where the disease has been confined to the region of the ileo-cecal valve.

In that class of cases represented by the patient with chronic obstruction, there is certainly room for a very wide and honest difference of opinion. If left until the obstruction is nearly complete, the growth has too often spread by contiguity or metastasis, until its complete and thorough removal is impossible. Interference under such conditions may furnish the opportunity for the exhibition of great technical skill on the part of the surgeon, but can hardly be of any substantial benefit to the patient, and too often supplies the sort of failures which are contained in Dr. Fitz's paper, to the discredit of surgery.

Much the same can be said of those cases in which operation is undertaken only after the discovery of a palpable tumor. When the disease has reached a point where the diagnosis is only too apparent, surgery is unlikely to afford any great measure of relief, and even an exploratory incision should be undertaken very cautiously, if at all.

In these cases, before the appearance of obstruction or tumor, it will usually be found that there have been for a longer or shorter time, symptoms of intestinal indigestion, abdominal pain, constipation often alternating with diarrhea and other intestinal disturbances, which, in the light of the later developments, were their forerunners.

I believe there is a time in every case of cancer of the intestine, as of cancer in other more exposed parts of the body, when the growth is local and can be removed with reasonable probability of a very long immunity from recurrence, and it is to a study of these earlier symptoms, with a view to the recognition of this earlier stage, that we must invoke the hearty co-operation of our medical friends, for that is the appropriate time for surgical interference.

I would confine the exploratory incision, then, to those cases in which the earliest symptoms were those of acute intestinal obstruction, of appendicitis, acute or chronic, and to those cases of chronic intestinal disturbance in which there was a clear presumption that malignant disease, if it existed, had not advanced beyond the point where its radical removal was impossible.

So, too, after exploration and the discovery of a malignant growth, I would stop there, where the disease was found to have invaded the mesentery, its lymphatics, the adjacent peritoneal surfaces by adhesions, or other organs by metastasis, to an extent to make its complete and radical removal unlikely. It happens often enough here, as elsewhere, that cancer has invaded adjacent structures even when its presence cannot be detected by sight or feeling. I would reserve the radical operation for those cases in which the disease, so far as gross appearances are concerned, can be wholly isolated and removed.

I have said little of the palliative operation of colostomy and the various forms of intestinal anastomosis and exclusion, because I feel that if the growth cannot be removed with a fair assurance of immunity from recurrence there can be but little relief or satisfaction in a few weeks or months of added life with the burdens of a fecal fistula or a more or less imperfect anastomosis. Such an existence, short and full of suffering as it so often is, may be important enough for some special purpose to make one or the other of these operations necessary or desirable.

Colostomy in particular may be necessary for the relief of acute intestinal obstruction, or under other conditions as a preliminary to resection, but in the advanced stages of the disease none of these operations can afford more than a very temporary and imperfect relief, and they belong, it seems to me, to the surgery of the mechanic, not of the Samaritan.

DISCUSSION.

DR. F. S. WATSON of Boston: I want to say one word only with regard to that part of Dr. Gage's paper which deals with the question of making an artificial opening in the bowel as a palliative measure in inoperable cases of malignant disease of this locality. I cannot agree with either the reader or with Dr. Fitz, whom he quotes, with regard to this point, that it is not worth while to do colostomy under such circumstances.

Dr. Fitz gives, in the paper referred to by Dr. Gage, an entirely erroneous judgment with regard to colostomy as a measure of relief in these cases. Colostomy performed as Mayo recommends, on the same principle as that of the Ssabana Jew Frank gastrostomy in cases of cancer of the stomach, uniformly affords very great comfort to the patient, and does not simply prolong life at the expense of substituting a condition so disgusting and obnoxious to the patient

and to those who care for him that it is worse than that produced by the disease left to itself.

It is true that we cannot relieve the pain which is due to the pressure of the tumor, but why we should allow the patient previous to that time, or for that matter after it is present, to support the additional suffering which arises from the distention due to obstruction, or that which proceeds from the passage of feces over an ulcerated surface, when we have the power to remove both by an operation which when properly done, controls the action of the bowels perfectly in the majority of cases, and removes all fecal matter from contact with the diseased area, is more than I can understand. It seems to me that it would be quite as reasonable to permit a patient to die of suffocation during diphtheria in a hopelessly fatal case, rather than to supply to him the ease furnished by a tracheotomy, and thus take that sting out of the load of distress to be sustained before death comes. I am confident that any of us who was suffering from the great pain of distention in obstructive cancerous disease of the bowel would call pretty loudly for the relief of colostomy if he had ever seen it given to another under such conditions.

Dr. A. T. Cabot of Boston: Dr. Gage's paper I think shows very clearly that what we need is not fewer but earlier operations; and that if our medical brethren would teach us how to discover these cases earlier, rather than point out cases which we lose because they have come to us too late, we might hope to advance in the direction of cure. We know that in these cancers at that part of the intestine which is accessible to constant examination in the lower bowel and rectum, there is a stage during which a radical removal is a cure. I have a number of patients now well from whom I have removed adenomata, adeno-carcinomas of the lower bowel. If you could learn the existence of these growths of the higher bowel during that stage, the removal would be quite as easy, even more so, because the bowel is less attached to the parts about. It seems to me the thing we must seek for is a closer observation of cases during the earlier stage of obstructon,— partial, recurrent obstruction,— because these patients often give a history of obstipation that amounts almost to obstruction which with castor oil passes off, and then two or three months later they cannot get movements with castor oil, and are turned over to the surgeon. I think we ought to work towards better diagnosis of the earlier stages. Whether we are going to get that by examination of the feces or how, I cannot say; but it seems to me it is "up to" our medical brethren to help us in that way rather than by criticising the cases which, coming to us too late, do not result favorably.

Dr. Gage: I am well aware that there is room for a wide and honest difference of opinion in regard to these palliative operations. In my own experience, even if immediate relief is obtained, the suffering is simply postponed, and even then the relief is very incomplete. The pain and discomfort incident to the continued pressure and extension of the disease are still very much in evidence, even if the acute obstruction is overcome.

Personally I should rather go without the operation, unless the disease could be radically removed or there was some special reason for which I wished to live a few weeks longer.

THE RELATIONS EXISTING BETWEEN RESPIRATORY AND INTRAPELVIC DISEASES.[1]

BY DANIEL H. CRAIG, M.D., BOSTON.

In 1878 Professor Skene,[9] in his inaugural address, called the attention of the New York Obstetrical Society to the very common occurrence of prolapse of the ovary, and requested the members to devote their energies to the discovery of the causes of this lesion in cases in which the cause was not manifest and in which the prolapse was unassociated with either disease in the ovary itself or uterine displacement. During the ensuing year, Drs. Mundé [12] and Goodell [13] each presented monographs upon the subject, not only considering the causes, but also the course, symptoms, diagnosis and treatment. Various authors have contributed to the subject since and practically all have quoted the list of causes as given in the above papers, and it is because I feel that I can aid a cause which will account for cases not explained by any causes mentioned heretofore that I have undertaken the work, of which I trust you will consider this as but a preliminary report.

Clinically, the condition is of immense importance, for Mundé [12] found uncomplicated prolapse in practically 10% of his cases and they are even more frequent now. In the last five hundred cases of pelvic disease personally diagnosticated I have found prolapse of the ovary to play a clinical part as follows:

Total number of cases 500.		
Cases in which ovarian prolapse was not a factor	296	or 59 %
Cases in which the uterus was retrodisplaced, the ovaries *not* being coincidently prolapsed	62	or 12½%
Cases in which retrodisplacement and ovarian prolapse coexisted	69	or 14 %
Cases in which ovarian prolapse existed with no retrodisplacement of the uterus	73	or 14½%
	500	100—

The increase of 4% in the frequency might be accounted for by the recent greater prevalence of respiratory diseases incident to the annual epidemics of influenza, which had not occurred at the time of Mundé's paper in 1879.

My attention was first directed to the relations existing between respiratory and intrapelvic lesions by the fact that patients with pelvic lesions, and especially those with ovarian prolapse, were invariably made worse and their favorable progress under treatment arrested by the intercurrence of any cough-accompanied lesion. In accordance with this conception

[1] Read before The Massachusetts Medical Society, June 10, 1903.

particular attention was given to the question of antecedent respiratory lesions in all cases in which ovarian prolapse obtained, and especially in those cases specified by Skene in which no cause was manifest. Positive histories were obtained too frequently to allow of its being considered merely coincidental. Very many histories might be adduced to substantiate this statement, but I have chosen three which seem sufficient for the present need.

CASE I. M. B. M., single, aged twenty. Never pregnant. Never any pelvic infection. For a few months acted as clerk in a drug store. For two years has been "running down." Family history strongly tubercular, but father and mother and one sister living and free from tuberculosis. Three years ago had enlarged glands removed from cervical region. Three small glands now palpable on right. Takes cold easily and always has persistent cough following each cold. Cough has at times persisted for months until phthisis was feared. About one year ago began to suffer from backache and leucorrhea and pain in iliac regions. Catamenia began at thirteen. Regular until recently. Painless. Duration five days until recently; now three or four days. Two napkins a day. No clots. Leucorrhea variable in amount and not absolutely constant. Exertion increases leucorrhea, which is then thick and yellowish. Has used douches. Not much backache now, but severe at times. Appetite poor. Digestion fair. Bowels fairly regular. Micturition normal.

Physical examination. — Chest and abdomen negative. Hymen intact but distensible. Nulliparous. Cervix long and conical. Uterus in good position, not enlarged nor tender. Some thickening of the right broad ligament. Left tube and ovary prolapsed and the ovary slightly enlarged [cystic?].

CASE II.— B. E. B. Single. Aged twenty-four. Never pregnant. Family and past history irrelevant. Catamenia began at twelve. Rather irregular, often varying between three and five weeks. In spring of three past years has menstruated every two or three weeks. Painless. Duration six to seven days, using thirty napkins, which are well saturated. Clots are frequent, their evacuation being accompanied with pain. Last April (date of history, Sept. 9, 1899) after a severe attack of la grippe, in which she narrowly escaped pneumonia, she suddenly began to feel pressure in the head, most persistent at the vertex. This vertical pain has been constant since. Worse at times. Often disturbs sleep, pain being worse at night. Can get no specific history. Paternal grandfather lived "a sporty life." Vertigo. Constant leucorrhea, sufficient at times to demand protection and of a thick, whitish character. Bowels regular. Micturition normal. General health good except that she is subject to winter cough. Appetite good. Digestion good.

Physical examination.— Thorax and abdomen negative. Perineum and cervix nulliparous. Uterus slightly enlarged and slightly back of the normal axis and decidedly tender. No discharge from os. Right tube thickened but ovary not felt. Left ovary prolapsed at side of cervix and slightly movable, being apparently loosely adherent.

CASE III. C. S. Married eleven years. Aged thirty. Has had two children and one miscarriage. Oldest child ten and the youngest three. Miscarriage resulted from a fall. First catamenia at fifteen. Always irregular, but much more regular the past two years. Duration seven to nine days. One to two napkins a day. Severely painful at times, necessitating rest in bed. Pain principally in right iliac region. Nearly constant lumbar and sacral backache, which is increased by walking and relieved by lying down. Constant but not excessive leucorrhea. Severe and frequent headaches. Bowels constipated. Micturition normal. Nervous and irritable. General health poor. Has many times feared consumption and has been almost constantly under medical care for pulmonary troubles. Has spent winters in the South to avoid lung troubles. Has raised blood at times.

Physical examination. — Lungs now clear. Heart normal. Uterus in normal axis and very little enlarged. Perineum good. Cervix lacerated, everted and eroded. Right ovary in the posterior cul-de-sac and enlarged, very tender and firmly adherent. Left ovary enlarged and soft.

These histories were chosen because in them the factors which have heretofore been most frequently assigned a causal rôle, perfectly correctly, are so markedly conspicuous by their absence. And here permit me just a word as to my position. I am not attempting to controvert the work already done on this subject, but to amplify the knowledge by the addition of one more etiological factor. Without doubt every one of the causes thus far mentioned, and especially those of Mundé [12] and the eleven enumerated by Goodell,[13] are all equally or more important.

Goodell,[15] in speaking of the causes of ovarian prolapse, summarizes his views in one terse sentence in which he says that any condition which causes a persistent congestion of the ovary should be considered a cause of its prolapse. Authors are unanimous in stating that the most frequent cause is arrest of involution post-partum, leaving the broad and ovarian ligaments in a relaxed, inelastic condition. In the above three cases, however, not one of the more active ordinary causal factors is present, and the only one of Goodell's eleven present is a lacerated cervix, which I feel sure was placed in the list mainly for the sake of completeness.

But two of these cases had never been pregnant nor infected and were virginal, showing no evidence of any form of sexual excitation. In the third no sign of subinvolution existed, any enlargement in the uterus being readily accounted for by the cervical and ovarian condition.

Study of the mechanism of cough will show that it most abundantly satisfies the causal requirements, first as to congestion and secondly, as I hope to show below, as to the force necessary to push the ovary downward. Westbrook [27] has

clearly and concisely described the mechanism of cough, and the following is an abstract of his article:

The muscles of respiration, with the exception of the diaphragm and levatores costarum, are attached to and act upon the upper ribs; the expiratory group make their principal traction upon the lower portion of the thorax. The expiratory group, in which we are particularly interested, are anteriorly and laterally the triangularis sterni above and the recti, obliqui and transversalis abdominis below. The action of the triangularis is simple and in this connection relatively unimportant. The action of the rectus is also simple. Its sole influence is to draw the sternum downward and so to diminish the size of the anterior wall of the abdominal cavity. The action of the obliqui is more complicated; their posterior portions, which pass directly from the crest of the ilium to the ribs exert an immediate and powerful downward traction upon the thoracic walls, not only diminishing the size of the lateral walls of the abdomen, but acting as adductors to the ribs, which have been put in abduction during inspiration. The more anterior portions have a crossed action and make diagonal traction across the abdomen. The upper portion of the external oblique and the middle portion of the internal oblique of the opposite side, attached as they both are to the intervening sheath of the rectus, are equivalent to one long diagonal muscle, passing from the ribs on one side to the crest of the ilium on the opposite side and capable by its contraction of drawing the ribs downward and inward so as to contribute much toward the expiratory diminution of the thoracic and abdominal cavities.

The function of the transversalis is equally important. Its middle portion is attached by strong fascia to the transverse processes of the lumbar vertebræ; while the fibers below arise from the iliac crest and outer half of Poupart's ligament. Above, it arises from the inner surfaces of the costal cartilages. The fibers of this part of the muscle pass horizontally across the abdomen and by the mutual attachment of those of the opposite sides at the linea alba, one continouus muscle is formed, the contraction of which strongly adducts the lower costal cartilages and thus diminishes the epigastric angle. The middle portion of the transversalis acts directly upon the abdominal wall. In its contraction the transversalis acts from the outer border of the quadratus lumborum, as that muscle fixes its tendons in the lumbar region. It tends first to draw the linea alba toward the fixed point; but the antagonism of the opposite side prevents lateral displacement and simply allows the anterior abdominal wall to approach the vertebral bodies, shortening the antero-posterior diameter. The muscular fibers intermediate between the anterior and posterior attachments make strong lateral compression. The lower fibers when they contract tighten the line across the abdomen and compress the intestines.

The posterior muscles are the erector spinæ, serrati postici and quadratus lumborum. When the erectores spinæ contract they draw the ribs forcibly downward toward the pelvis, lessen the transverse and antero-posterior diameters of the thorax and at the same time tend to shorten the perpendicular axis of the abdomen.

When these powerful muscles of expiration are spasmodically contracted, as in the act of coughing or sneezing, their first effect is to adduct and depress the ribs and by so doing diminish the size of the thorax in all its diameters. But as the abdominal walls only yield in the upward direction and as the contents of the abdominal cavity are practically incompressible, its roof, the diaphragm, which is relaxed during expiration, must ascend and encroach upon the thoracic space, from which air escapes, to compensate for the diminution in its size. The second effect of the expiratory contraction is to lessen the circumference of the abdomen. As the contents are incompressible and as the sphincter muscles, by their contraction, prevent the escape of the contents of the hollow viscera, the decrease in the transverse and antero-posterior diameters must be compensated for by an increase in its long diameter, another factor in the ascent of the diaphragm. Further, during the expiration of cough the glottis is partly closed, thus producing considerable resistance to the egress of the air.

Thus by making a more or less rigid walled cylinder of the abdomen, of which the top is to be elevated by internal pressure, the ascent of this top being resisted not only by gravity but also by a partial closure of the glottis, it is readily understood that the bottom of this cylinder is struck a veritable blow by *contre coup*. Speaking of this effect Westbrook says: "In the pelvis the inferior hemorrhoidal veins and those of the uterus, vagina and bladder are sometimes so turgid that slight ruptures and hemorrhages occur, particularly from the uterus, causing a bloody, serous discharge from the vagina during cough. Involuntary urination also sometimes results from the sudden downward pressure, especially in women."

Weiss [76] (*Heilkünde*, Vienna), as evidencing the expulsive power of this muscular mechanism, says: "The expelling speed of the air varies considerably. In quiet respiration it passes through the glottis at 125 cm. per second, and the pressure supports 2 mm. of mercury. During violent expiration and coughing, the pressure rises to 150 to 200 mm. and the speed is said to exceed that of the wind in a storm. It is said to be as much as 100 meters a second."

Westbrook's article was written apropos of respiratory diseases, but if it had been his desire to defend such a contention as is suggested by the present paper he could hardly have written more directly to the point.

In operating in or through the vagina no one can fail to note the marked rise and fall of the vaginal vault with each respiration, and if perchance the patient cough or vomit, the specula are not infrequently forced entirely out of the vagina. This impulse caused by cough is also plainly evident if a patient coughs during a digital examination.

Moreover the effect of respiratory influence has long been recognized in various pelvic lesions, particularly herniæ and uterine displacements, but no mention, so far as I am able to learn, has been made in connection with genuine respiratory diseases. This is true of both monographs and textbooks, both old and recent. The respiratory influence most frequently invoked is invariably a secondary one in connection with either the straining due to muscular exertion or that due to intestinal diseases. Almost every author who has written at all comprehensively of displacements of the pelvic viscera has cited straining as a cause. Yet the effect of straining on the pelvic organs is entirely respiratory, being wholly due to the involuntary holding of the breath in inspiration which invariably accompanies the muscular strain. The principal difference existing between the mechanism of strain and that of cough is in the degree of force, and that in straining the glottis is completely closed, with or without the relaxation of the sphincters.

The clinical evidence appearing so conclusive, the actual demonstration and measurement of the relation existing between respiratory causes and pelvic effects was all that was lacking. To supply, very crudely it is true, this want, I have constructed this apparatus, which, notwithstanding its humbleness, I have christened the pelvio-respirometer.

By its use I have been able to read exactly the force of the downward impact upon the pelvic structures resultant from various respiratory movements. Readings have not been made from a large number of subjects, because, as I expected, I found that the figures varied only within very narrow limits, and the readings given represent the mean average reading, with the maximum and minimum extremes only an ounce or a fraction of an ounce above or below.

Before giving the readings, however, I wish to say just a word as to what was to be expected. Many of you have undoubtedly, as I have, seen the so-called "lung-testing" machines commonly placed in public places, the dials of which show how many pounds pressure can be created by forcible expiration. All that I have seen are shamefully mendacious. The average expiratory power for an adult man is 1½ lbs. By training and special gymnastic expansion of the chest a few ounces can be gained. In the adult woman the average expiratory power is 11½ oz., the maximum personally noted being 14 oz. With this explanation I submit the readings obtained by the use of the pelvio-respirometer.

Downward pressure is produced upon the pelvic viscera as follows:

Ordinary inspiration causes a downward intrapelvic pressure of	1.85 ounces
Ordinary expiration a vacuum of	7–16 inch
Forced inspiration a pressure of	2.56 ounces
Forced expiration, a vacuum of	13–16 inch
Slight cough a pressure of	7.5 ounces
Violent (artificial) cough a pressure of	16.3 ounces
Moderate straining a pressure of	6.83 ounces
Strenuous straining a pressure of	10.95 ounces

So that the conditions might as nearly as possible simulate the ordinary conditions, these readings were all made with the patients sitting erect and with the corsets on. One other fact I wish particularly to specify; no readings have been made in cases in which a genuine hard cough due to actual respiratory lesions existed. Much as I desired to do this and also to measure the pelvic effects of sneezing, I feared to allow my enthusiasm to carry me thus far on account of the possibility of sufficient pressure being brought to bear on the fluid in the vagina to force it through the fimbriated ends of the tubes into the peritoneum. I mention sneezing because but for the trespass upon your time I should have detailed one history in which an attack of hay-fever was the direct exciting cause of the symptoms which were due to an uncomplicated prolapse of the left ovary.

The effect of genuine hard cough of bronchitis, for example, certainly far exceeds that of the counterfeit, and yet I think you will agree that a persistent repetition of such force as has been shown to be engendered in the artificial cough would be quite sufficient to in time drive the ovary down.

Moreover, a study of the topographical anatomy of the pelvic contents shows still further reason for this action of cough. Prolapse of the left ovary is slightly more common than of the right, the reason usually assigned being its greater proneness to congestion owing to its venous return circulation. This reason is undoubtedly active and is only supplemented by the relations of the sigmoid flexure as described by Deaver.[78] He says: "Normally, owing to its long meso-sigmoid, the greater part of the sigmoid is an occupant of the pelvis. *Here it lies in contact with the bladder, the uterus and its appendages,** and those coils of the small intestines which occupy the pelvis." The attachment of the sigmoid being posterior, if it is in relation with the bladder it must cross the top of the left broad ligament in an antero-posterior direction. Consider what must occur when this sigmoid is driven downward by the effects of coughing, or even straining, especially if this sigmoid is loaded, as so frequently occurs in women. But this downward impact represents only one or two equally important factors. According to Westbrook, the mechanism of cough is such as to exactly supply Goodell's one general predisposing cause, namely congestion.

We have also thus far been considering the effect of cough on normal ovaries. Consider now how much this effect is heightened in the instance of an ovary already predisposed to prolapse by pre-existing lesions. Consider, for example, its effect upon an ovary enlarged, heavy and turgid with the physiological congestion of menstruation, or enlarged and heavy from the presence of a false corpus luteum, or again an ovary but imperfectly sustained by broad and ovarian ligaments weakened by arrested involution, and does not the evidence seem conclusive?

And of all the causes of ovarian prolapse respiratory lesions are certainly amongst the most

* The italics are my own.

important. First, because in our New England climate catarrhal conditions of the respiratory tract, accompanied by more or less persistent cough, are so common as to have by familiarity bred a certain degree of contempt, especially in the laity. Secondly, because this is a cause which does not act insidiously and unsuspectedly, but frankly and openly, thereby offering the greatest possible scope for the highest attainment of medical science; namely, the prevention of disease.

But before proceeding to the consideration of the prevention of complications, I wish to offer one other suggestion. Throughout the literature of the subject I find comparatively frequent reference to congenital ovarian prolapse. My suggestion is that these cases may be better accounted for. In congenital malformations several factors generally act conjointly and it is anatomically difficult to understand how any such action can produce *downward* and backward congenital ovarian displacement. Ovaries are congenitally unquestionably displaced anteriorly, as in Engelmann's [15] cases and into hernial sacs, but where such conditions as persistence of the lumbo-ovarian ligament or the existence of the appendiculo-ovarian ligament of Clado obtain, the ovary is maintained above its normal level.

May not at least a part of these co-called congenital prolapse cases be due to the congestion and pressure effects of respiratory diseases — for example, whooping-cough — during childhood, no symptoms manifesting themselves until after the maturation of the organs?

If we grant that the above deductions are correct, at least in part, much can be done, especially in women known to be the subjects of pelvic lesions, by prompt and efficient attention to the respiratory lesions; and if for any reason it is inadvisable or impossible to inhibit the cough, much may be done to lessen its evil effects upon the pelvic viscera. And I say pelvic viscera advisedly, for while I have confined myself to-day entirely to the ovarian conditions, you can all easily see the concomitant influence on the other pelvic structures.

The prevention of pelvic complications of respiratory lesions rests not with the gynecologists but with the general practitioner, for it is he who sees the cases long before he needs to refer them to us.

The following suggestions may, with others better known to the general practitioner than to us, serve to avoid such complications:

The congestion of menstruation acting in conjunction with that of cough is always harmful and even the nulliparous should be guarded against it. As corsets lessen decidedly the normal abdominal resiliency and go far toward destroying the so-called retentive power of the abdominal mechanism, they had better be proscribed during any severe and long persisting cough-accompanied lesion, especially during the catamenia.

By requiring a patient to assume the prone position for a few minutes after a violent coughing spell, disengorgement of the pelvic vessels is favored and gravity assists the ovarian supports.

If ovarian, or pelvic, involvement is suspected much good may result from the employment of the pelvic respiratory massage as suggested by Williams. This consists in having the patient assume the genu-pectoral or knee-elbow position and aspirate the pelvic vessels by slow force-expiration about fourteen times a minute.

Complications may also be avoided in those already the subject of pelvic disease, by insistently warning them of the necessity of avoiding a cough and the importance of prompt and efficient attention should such a condition arise.

ADDENDUM.

Having pursued this study thus far, which, by the way, I consider as probably only the beginning, I naturally desired to know if the downward impact of practically one pound, as shown by the pelvio-respirometer, was really sufficient to throw the ovary down. While I do not consider my data as conclusive as yet and shall investigate the matter further, I have, since the completion of the paper, thanks to the kind co-operation of Professors Thayer, Cushing and Leary, been able to make a series of investigations on the cadaver and learn that in the dead subject a pressure of 10 oz. is sufficient to carry the fundus of the uterus to the bottom of the cul-de-sac of Douglas. A slightly greater force is requisite to so completely prolapse the ovary. It is carried down to the level of the utero-sacral ligaments by a pressure of 12½ oz. and is completely prolapsed by a pressure of 14 oz. The normal vital ligaments would undoubtedly act slightly different from those on the cadaver, but if the respective resistance imparted to the hand is of any value the ligament on the cadaver seemed much more resistant than are those ordinarily felt in operating, but of course totally lacking in resiliency.

Taking these findings as a basis, it appears that the force engendered by cough is slightly in excess of that required.

CARCINOMA OF CHOROID METASTATIC FROM PROSTATE.

BY ALLEN GREENWOOD, M.D., BOSTON,

Ophthalmic Surgeon, Boston City Hospital.

W. G. C., age fifty-six, came to the eye clinic of the Boston City Hospital Sept. 29, 1902, and the following history was obtained:

Born in Pennsylvania. Hotel clerk.

Family history. — Mother and father dead; cause unknown. Sister alive and well.

Past history. — He entered the Boston City Hospital Oct. 9, 1901, in the service of Dr. Munro, for difficulty in urination. The records show a diagnosis of hypertrophy of prostate, with a history of difficulty of urination covering a period of ten years and for a year more or less dribbling of urine.

Physical examination at that time is recorded as follows: Obese, color fair. Pupils small, but react. Tongue clear. Heart, systolic murmur over base with aortic second accentuated. Liver palpable about two fingers below. Abdomen prominent. Temperature 100. Pulse 110°.

Rectal examination. — Flat, broad prostate, not projecting, but slightly into rectum and upper end not within reach of finger. Operation advised and refused. Taught how to use catheter.

Present history. — Four weeks ago he noticed a dimness of vision of the left eye and went to an eye clinic, where he was told that he had a retinal separation. The vision became more and more defective until a week ago, when it was reduced to light perception accompanied by severe pain in eye and all over left side and front of head. The pain was much worse at night. He also complained of great weakness and shortness of breath. Has lost sixty pounds in one year.

Examination showed a well-developed man, but poorly nourished and very anemic to the point of cachexia. Right eye normal. Left eye presented a marked circumcorneal injection, pupil widely dilated and cloudy looking, iris muddy, cornea steamy and anesthetic, and tension plus; fundus could not be seen on account of cloudy media, perception of light only. Under use of eserin and cocaine the pain and injection diminished.

On Oct. 6 I first saw the case and by that time, though the tension was still plus and the eye showed all the signs of acute glaucoma, the media had cleared enough under the eserin to allow a view of the fundus. The ophthalmoscope showed a separation of the retina in the upper temporal quadrant extending into the lower quadrant, beyond which the retina could not be followed on account of vitreous haziness. The cause of the separation could not be made out by use of the ophthalmoscope, but the clinical history of localized retinal separation, followed by acute glaucoma and accompanied by beginning cachetic condition, led me to a diagnosis of choroidal tumor, probably sarcoma, with involvement of other organs, especially the liver. The treatment of the glaucoma with eserin was continued and the patient transferred to the medical wards for observation and treatment of his general condition.

The following additional facts were taken from the medical records:

Marked arteriosclerosis. No general glandular enlargement. Mucous membrane pale. Tongue protruded straight, considerable white coat.

Thorax. — Barrel-shaped. Some prominence of lower half right. Resonance good throughout. Some slight dullness at left apex. No apparent change of vocal fremitus. Expiration prolonged.

Heart.—Upper border in third space, right 5 cm. to right, left 9 cm. to left, of mid-sternum. Sounds best heard at fifth space inside of nipple line. Sounds clear, strong through-

out, save systolic murmur over aortic area. Action regular. Aortic second accentuation.

Pulse. — Regular, fair volume and tension.

Liver. — Dullness from fifth rib, edge palpable just below costal margin in nipple line. Surface smooth. No nodules felt.

Spleen. — Not felt.

Abdomen. — Markedly scaphoid. Superficial tissue very lax. Tympanitic. No tenderness or spasm.

Genitalia. — Apparently normal.

Extremities. — Reflexes present and equal. No edema. Tibia slightly rough.

Skin. — Dry, numerous pigmental, papillary, pea-sized growths on trunk and extremities.

The day after entrance patient's temperature rose to 101.8°, but soon became normal and then subnormal.

He was somewhat stupid, but roused to answer questions. Had some diarrhea. Had some cystitis.

Four days later it was noted that he had grown more feeble since entrance. Was rapidly emaciating and was not entirely conscious. Respiration very rapid. Failed more rapidly to-day than before. Pulse failed and he died at 7 P.M.

We were fortunate in obtaining an autopsy, including removal of the left eye, section of which showed carcinoma of choroid. The autopsy was performed by Dr. E. E. Southard, whose report follows. Dr. E. E. Jack of Boston reported a case of double metastatic carcinoma of the choroid, at the thirty-eighth annual meeting of the American Ophthalmic Society, which was published in the transactions. The following summary of reported cases is from Dr. Jack's report: Up to that time, including his own, there had been twenty-nine cases reported — "twenty-three females and five males, one clinical history unrecorded. Of these nine have been double and all but one in females. In the twenty-three females the primary tumor was in the breast in twenty-one, in the lungs and pleura in one and in the thyroid in one. In the five males, stomach in three, breast in one and lung in one." The case reported here adds another to the list of males and the first one with the primary tumor in the prostate. Another unusual feature was the occurrence of acute glaucoma.

A CASE OF CARCINOSIS WITH SECONDARY NODULE IN THE EYE.[1]

BY E. E. SOUTHARD, M.D., BOSTON,

First Assistant in Pathology, Boston City Hospital.

THE present report follows a clinical report by Dr. Allen Greenwood, to whom I am obliged for a number of suggestions. To Dr. F. B. Mallory, during whose service I made the autopsy, I am indebted for aid in the report.

(*a*) AUTOPSY FINDINGS: GROSS.

The examination was made twenty hours after death.

External examination shows an elderly man of fairly strong build and good musculature. Nutrition poor. Abdomen scaphoid. Moderate sclerosis of peripheral arteries. Pupils equal, 5 mm. wide. The only external sign of tumor is a mass, egg-size, immovable, under skin of left axilla.

Internal examination of trunk shows in —

Bony thorax. — Two tumor masses. (*a*) A low mound-like prominence at back of sternum, involving lower end of body and the xiphoid attachment, 5 by 1.5 cm., well encapsulated, of rather firm consistence, of a mottled pink and gray color with miliary china-white masses starting from cut surface. (*b*) A mass, orange-size, obliterating a portion of pleural cavity at left apex, replacing a portion of third and fourth ribs and continuous with mass palpable in axilla. No evidence of encapsulation. Substance injected, darker in color than sternal mass, but of same consistence.

Abdominal walls, retracted, with thin layer of fat.

Pleural cavities. — Numerous fairly firm old adhesions over all, but thicker and firmer at summits of the many subpleural tumor masses and inseparable at the left apex.

Pericardial cavity. — Moderate amount of amber fluid. Membrane normal save for grayish-black mass, 3 by 2 by 1 cm., bulging into and covered by parietal serosa in uppermost portion of sac, well encapsulated in front by mediastinal connective tissue.

Peritoneal cavity. — Serosa mainly unaltered. Fibrous adhesions overlie many coin-sized and umbilicated tumor masses in liver. A smooth fibrous band striking across space behind bladder, bowstring fashion, shows in the middle a dark gray tumor mass, pea-size. Bladder, moderately distended, rides high in pelvis. Reduction impossible, on account of tumor in prostate and on account of the firm union of bladder wall with symphysis pubis by a flattened tumor mass, 2 cm. thick, accurately fitting but not invading the two structures.

Heart. — Weight 350 gm. Epicardium thinly underlaid with fat. Muscle of good consistence. Left ventricle 1.5 cm. thick at a point 2 cm. below aortic valve; right ventricle 0.5 cm. thick at a point 2 cm. below pulmonary valve. Fibrillæ contain no fat. Endocardium chiefly normal; the mitral valve curtain shows a few slight yellowish mounds of sclerosis. The valves measure: tricuspid, 13.5 cm.; pulmonary, 7.5 cm.; mitral, 11 cm.; aortic 8 cm. Chambers contain cruor clots.

Lungs. — Right weighs 1,050 gm., left weighs 910 gm. Both lungs exhibit everywhere nodules, sometimes ill-defined, sometimes globular and from a few millimeters up to several centimeters in diameter, often of an ash-gray color with black vascular points, sometimes darker and of a reddish tint. The surface is emphysematous and retracted, according to the site of underlying nodules, in areas 2 to 3 cm. across. Section surface firm and almost dry. Two thirds to three quarters of air space is replaced with tumor. Peribronchial lymph nodes enlarged to size of fist, but the nodal composition is preserved; from the cut surfaces start white miliary masses on slight pressure. Pigment-bearing tis-

[1] From the Pathological Laboratory of the Boston City Hospital.

sue skirts the periphery of some of the enlarged nodules.

Spleen. — Weight 130 gm. Unciform projection below 4 cm. in diameter. Capsule blue. Section surface beefy red and slightly pulpy. Trabeculæ evident. Malpighian bodies as gray points. Gastrointestinal tract normal except for nodule described above.

Pancreas normal.

Liver. — Weight 1,860 gm. Substance of a slightly yellowish brown riddled with opaque yellowish-white nodules, varying from pea- to walnut-size, globular within, superficially low and often umbilicated. Substance of the usual liver firmness; nodules somewhat firmer, in comparatively few cases centrally yellower and of softer consistence. Nodules show no trace of capsulation. The largest nodules occur toward and upon the under surface.

Gall bladder. — Bile dark. Two mulberry calculi, about 1.5 cm. in diameter.

Kidneys. — Weight 240 gm. (right 95, left 145). Strip with moderate difficulty. Interstitial pitting narrow but of fine mesh. Left kidney shows at upper pole an egg-sized, thin-walled cyst containing clear fluid. Fresh specimen shows no intra-epithelial fat.

Adrenals. — Left shows irregular distribution of medullary substance — a species of separate adrenal lying imbedded but not encapsulated in the cortex at the inferior pole.

Bladder. — Mucosa blackish, perhaps thickened, but not invaded by neoplasm.

Prostate. — If there is any normal prostate tissue, it is now indistinguishable from a firm egg-sized mass, through which probe cannot be passed or urine forced. Space between bladder and symphysis completely filled by the growth which rises just above the level of symphysis. The tissue is gray with a few vascular points and miliary whitish masses popping from section-surface. Upon the left iliac rim over iliac bifurcation is a boat-shaped mass of tissue resembling the prostate growth. Seminal vesicles and ejaculatory ducts not made out.

Aorta. — Moderate patchy sclerosis.

Organs of neck. — Trachea reddened.

Brain. — Weight 1,360 gm. Dura tense. Right side darker than left. Sinuses contain cruor clot. Dura peels with difficulty from right side. Pia of upper surface of frontal lobe replaced with a reddish-gray firm growth, 1.5 to 2 cm. thick; growth very vascular, in places hemorrhagic. The right frontoparietal region is overlaid with hemorrhage in which there may be organization or a thin layer of neoplasm. Convolutions of left side flattened, of right side marked with digitations radiating roughly from a point in the longitudinal fissure 5 cm. from anterior pole.

Eye. — The tumor occupies a spherical sector on the temporal side of the globe of the left eye. The tumor is composed of two lobes, fused at the base, and is 20 mm. by 6 mm. at the greatest width, advancing to a point 4 mm. back of the ora serrata and failing to involve the nerve head by 2 mm. The sclera is of the usual thickness on all sides and is not involved. The choroid coat merges indistinguishably into the tumor; the pigment cannot be told in color from rather wide darkened areas in the tumor considered at time of autopsy as hemorrhagic in origin.

(*b*) MICROSCOPIC FINDINGS.

Following are the microscopic findings in the main organs:

Heart. — Perinuclear pigmentation of a few fibers.

Lungs. — Pleura injected. Small interstitial collections of pigment. Capillaries everywhere deeply injected. Considerable diapedesis into many air spaces. Pigment-bearing macrophages in many air spaces. Neoplasm prominent, confined in plane of section to certain acini. The tumor spreads from space to space in continuous masses, coarsely and smoothly lobulated by the intact septa. The tumor is here and there constricted by the re-entrant septa, so that the cells become elongated and compressed. The cells are in the main oval; their outlines are indistinct except at the free border of the tumor. The nuclei are quite regularly oval or a trifle acuminate, vesicular and provided with one or more deeply staining round or oval nodes suspended at some distance from nuclear membrane by numerous chromatic threads. The nuclei often lie free in rounded spaces in the cytoplasm. At some foci the tumor breaks up into more deeply eosinophilic masses with dead-black nuclear remnants.

Spleen. — Trabeculæ and reticulum increased in amount. Capillaries packed with blood corpuscles. Phagocytes containing masses of blood corpuscles, often fused together and colored a deep brown, are prominent, apt to occur in groups, often in the adventitia of the vessels of the Malpighian bodies. Similar pigmentary masses occur in the capsule. The vessels of the Malpighian bodies frequently show hyaline changes in media.

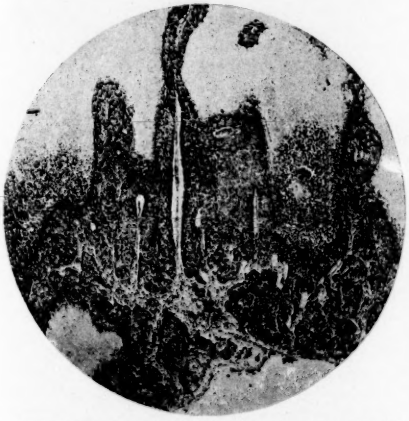
The tumor masses are rounded and lobulated, preferring to spread through the pulp, sparing both trabeculæ and Malpighian bodies. The cells resemble those described with the lung. Masses of acidophilic débris are common inside certain lobules. Mitoses frequent.

Liver. — Section of liver with small tumor nodules.

Perilobular tissues in the main normal. A certain number of branches of portal vein are dilated by masses of cells occasionally in mitosis. A slight degree of lymphoid infiltration around the vessels containing tumor.

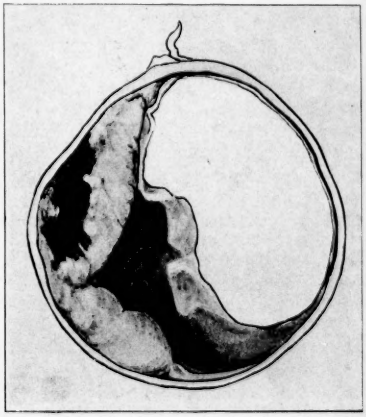
Capillaries filled with blood. Parenchymal cells granular and centrally or diffusely pigmented.

The tumor mass contains numerous mitoses. The individual cells resemble those described under lung; but they are grouped in smaller masses to suggest alveoli with a thin stroma. Toward periphery of nodule the thin stroma begins to contain remnants of liver epithelium. The tumor has a finely serrate edge: the tumor pre-



fers to invade capillaries or pericellular spaces. The portal canals are spared by the tumor and may be made out deep in the tumor mass with the portal veins containing tumor thrombi.

Kidney. — Islands of interstitial overgrowth with collections of lymphoid cells. Moderate diffuse interstitial overgrowth, well marked in pyramids. Arteriosclerosis with areas of fibrous overgrowth and atrophy of tubules in association with the vessel. The dilated tubules contain



growth in the lung. The growths in the pia and in the eye must be grouped together from their tendency to the papillary form. The tendency to hemorrhage shown by the pial growth is remarkable and is probably due to local compression of the veins. Notable also is the choroidal pigment deep in the stroma of the nodule of the eye.

From anatomical and histological evidence alone, one would scarcely be warranted in assigning the prostate as the original focus of tumor

A CASE OF CARCINOSIS WITH SECONDARY NODULE IN THE EYE. — SOUTHARD.

Portion of carcinomatous nodule in the eye. Note papillary form. Intracellular pigment in stroma, *e. g.*, at base of tallest process.

Tumor occupies spherical sector on temporal side of left eye. Shown here in coronal section. Note pigmentation and detached retina.

prostate with extension into retroperitoneal pelvic tissues; carcinoma of intestine, liver, spleen, lung, mediastinum, thoracic cage, pia mater, eye; general arteriosclerosis; chronic interstitial and arteriosclerotic kidney.

Histologically the carcinoma is fairly constantly composed of —

(*a*) Smooth masses of cells having indistinct borders and a cytoplasm containing clefts or vacuoles in which lie oval vesicular nuclei with prominent nucleoli.

(*b*) A stroma varying extremely in amount from organ to organ. The minor differences are partly ascribable to locus: thus the finely serrate border found in the liver depends upon the rapid growth of the tumor in the parenchyma of that organ; with this may be compared the smooth lobular

therapy advanced in popularity, curiously enough, it was found that vibration, mechanically produced, again came forward and was received with more professional favor. It was not surprising, therefore, that at the last International Congress of Electro-Therapeutists held in Paris in July and August of 1900 — the year of the French Exposition — six instruments were there exhibited, all designed to apply mechanically produced vibration to the body. As none of these instruments were the equal in the point of merit to several upon the market of this country to-day, I will not detain you by describing their several mechanical features further than to say that they were designed and introduced by

[1] Read before the Medical Society of the Borough of the Bronx, New York, May 12, 1903.

sue skirts the periphery of some of the enlarged nodules.

Spleen. — Weight 130 gm. Unciform projection below 4 cm. in diameter. Capsule blue. Section surface beefy red and slightly pulpy. Trabeculæ evident. Malpighian bodies as gray points. Gastrointestinal tract normal except for nodule described above.

Pancreas normal.

Dura peels with difficulty from right side. Pia of upper surface of frontal lobe replaced with a reddish-gray firm growth, 1.5 to 2 cm. thick; growth very vascular, in places hemorrhagic. The right frontoparietal region is overlaid with hemorrhage in which there may be organization or a thin layer of neoplasm. Convolutions of left side flattened, of right side marked with digitations radiating roughly from a point in the longitudinal fissure 5 cm. from anterior pole.

Eye. — The tumor occupies a spherical sector on the temporal side of the globe of the left eye. The tumor is composed of two lobes, fused at the base, and is 20 mm. by 6 mm. at the greatest width, advancing to a point 4 mm. back of the ora serrata and failing to involve the nerve head by 2 mm. The sclera is of the usual thickness on all sides and is not involved. The choroid coat merges indistinguishably into the tumor; the pigment cannot be told in color from rather wide darkened areas in the tumor considered at time of autopsy as hemorrhagic in origin.

(*b*) MICROSCOPIC FINDINGS.

Following are the microscopic findings in the main organs:

Liver. — Section of liver with small tumor nodules.

Perilobular tissues in the main normal. A certain number of branches of portal vein are dilated by masses of cells occasionally in mitosis. A slight degree of lymphoid infiltration around the vessels containing tumor.

Capillaries filled with blood. Parenchymal cells granular and centrally or diffusely pigmented.

The tumor mass contains numerous mitoses. The individual cells resemble those described under lung; but they are grouped in smaller masses to suggest alveoli with a thin stroma. Toward periphery of nodule the thin stroma begins to contain remnants of liver epithelium. The tumor has a finely serrate edge: the tumor pre-

fers to invade capillaries or pericellular spaces. The portal canals are spared by the tumor and may be made out deep in the tumor mass with the portal veins containing tumor thrombi.

Kidney. — Islands of interstitial overgrowth with collections of lymphoid cells. Moderate diffuse interstitial overgrowth, well marked in pyramids. Arteriosclerosis with areas of fibrous overgrowth and atrophy of tubules in association with the vessel. The dilated tubules contain granular débris and ring-reticula. The epithelium is granular, the nuclei small and black or absent, the cell-borders indistinct. Glomeruli pervious.

Prostate. — The prostate tissue is ill-preserved: tumor masses, smooth, round and homogeneous in character of cells contained, lie imbedded in deep stroma.

Brain. — Section from frontal lobe with overlying tumor. Deep rounded masses of tumor cells set close with scarcely evident cell-borders interdigitate with deep trabeculæ of fibrous tissue. Nearer the cortex the true pia comes more in evidence with collections of blood corpuscles, lymphoid cells and enormous numbers of pigment-bearing phagocytes. Extreme overgrowth of subpial glia.

Eye. — Section from eye shows a tumor growth resembling that overlying the brain. The papillary masses are not so thick as in the pial growth; they grow in places, characteristically in deep, slender, fjord-like clefts. Cells containing choroidal pigment are found in the slender connective tissue stalks several millimeters distant from the choroid.

There is little differentiation of cells within the masses. The cell-borders are usually indistinct; but show in places as rounded or polygonal cells occasionally drawn into processes. The nuclei are rounded or oval, have a distinct membrane and are supplied with very distinct, rather coarsely-meshed network with several large condensed masses of chromatin. The tumor shows in places fragmentation and degeneration, in other, sometimes closely adjacent, places, many karyokinetic figures.

(*c*) PATHOLOGICAL SUMMARY AND DISCUSSION.

Anatomically the case shows carcinoma of prostate with extension into retroperitoneal pelvic tissues; carcinoma of intestine, liver, spleen, lung, mediastinum, thoracic cage, pia mater, eye; general arteriosclerosis; chronic interstitial and arteriosclerotic kidney.

Histologically the carcinoma is fairly constantly composed of —

(*a*) Smooth masses of cells having indistinct borders and a cytoplasm containing clefts or vacuoles in which lie oval vesicular nuclei with prominent nucleoli.

(*b*) A stroma varying extremely in amount from organ to organ. The minor differences are partly ascribable to locus: thus the finely serrate border found in the liver depends upon the rapid growth of the tumor in the parenchyma of that organ; with this may be compared the smooth lobular growth in the lung. The growths in the pia and in the eye must be grouped together from their tendency to the papillary form. The tendency to hemorrhage shown by the pial growth is remarkable and is probably due to local compression of the veins. Notable also is the choroidal pigment deep in the stroma of the nodule of the eye.

From anatomical and histological evidence alone, one would scarcely be warranted in assigning the prostate as the original focus of tumor formation. But the case as a whole — taken clinically as well as pathologically — seems to warrant interpretation as a case of carcinoma of prostate with multiple metastases.

MECHANICAL VIBRATION: ITS THEORY AND APPLICATION IN THE TREATMENT OF DISEASE.[1]

BY MAURICE F. PILGRIM, A.B., M.D., NEW YORK,

Professor of Psychiatry in the New York School of Physical Therapeutics; First Vice-President of the American Electro-Therapeutic Association.

In presenting briefly to you this evening the theory and application of mechanical vibration in the treatment of disease, I feel that I am not asking your attention to a new physical method of treatment so much as to the revival of an old but now greatly improved therapeutic agent.

Attempts in the treatment of disease by more or less crude and clumsy mechanical vibratory methods were made as far back as forty years ago. Little if any progress was made, however, and they received slight recognition from the profession at large. Two reasons were responsible for this: First, the treatment was applied more or less empirically and without much reference to any well-defined principles of physiology. Second, it began what little development it subsequently attained, at about the time electricity was beginning to come forward as a curative agent. Whatever virtue it may have possessed in these earlier years, was obscured by this agent, which, if not more capable therapeutically, was at least applied with more definiteness of purpose and a greater regard for those principles of physiology which then, as now, were believed to govern the functionation of the human body. But as electricity as a therapy advanced in popularity, curiously enough, it was found that vibration, mechanically produced, again came forward and was received with more professional favor. It was not surprising, therefore, that at the last International Congress of Electro-Therapeutists held in Paris in July and August of 1900 — the year of the French Exposition — six instruments were there exhibited, all designed to apply mechanically produced vibration to the body. As none of these instruments were the equal in the point of merit to several upon the market of this country to-day, I will not detain you by describing their several mechanical features further than to say that they were designed and introduced by

[1] Read before the Medical Society of the Borough of the Bronx, New York, May 12, 1903.

eminent French electro-therapeutists, among whom may be mentioned Drs. Garnault, Boudet, Gilles de la Tourette, Larat and Gautier. Dr. Charcot had on exhibition what was known as the "Vibrating Table of Charcot and Gilles de la Tourette," which was the best instrument of its kind shown there. When a little later in this paper we come to consider what scientific mechanical vibration really is and demands, you will observe how crude even Charcot's conception of such an instrument was. Employing this instrument, the patient was placed in a chair securely fastened to the platform, and the table or platform was then set in motion, which was more or less vibratory in character. The patient was thus given a pretty powerful "shaking-up," which was not, in reality, vibration at all as it is now understood or demanded for therapeutic purposes. The idea has been worked out in this country in the instruments which are being sold directly to the public, without appealing at all to the profession for support, and which they certainly very properly would not receive. Such instruments should more accurately be called "shakers," rather than vibrators, and are susceptible of producing quite as much harm as good.

Rapid progress has been made, however, along this line until we now have manufactured exclusively for physicians' use, and sold only to them, instruments which meet the scientific demands of practitioners, one of which it will be my pleasure to exhibit and demonstrate to you this evening.

In order to rapidly canvass the subject, it may be well to consider:

(1) What mechanical vibration is?

(2) How it can be most effectively applied?

(3) What it is capable of accomplishing when so applied?

Considered in its broadest sense, vibration is the most abounding, the commonest force in the universe with which we are familiar. Hearing and sight, for example, two of the most important functions of the body, are scientifically recognized as the result of the rapid vibrations in the universal ether. Physicists say that the ether here referred to is a medium filling all space, through which the vibrations of light, radiant heat and electric energy are propagated. The nervous system — spinal and sympathetic — which dominates the entire body, responds to and requires, at times, stimulation. Aside from the source of normal or natural nerve stimuli, there are several artificial methods of supplying it. Landois and Stirling, on page 76 of their Textbook of Physiology, in referring to this subject, say:

"The following are the various kinds of general nerve stimuli, that is, modes of motion which act upon nerves: (1) Mechanical; (2) thermal; (3) chemical; (4) physiological; (5) electrical."

They add: "Nerves possess the property of being thrown into a state of excitement or greater action and efficiency by stimuli."

It is a matter of repeated demonstration, familiar to us all, that pressure (which is in reality only a modification of a blow) imparts stimulus to a nerve. For example, light pressure exerted over the pneumogastric, just above the sternum, produces a cough — the effect of reflex pressure stimulation. So, too, a sharp blow over a nerve accelerates or stimulates its action, the degree being largely governed by its length and force. If greater pressure is made, a sedative effect ensues; and if the pressure is sufficiently prolonged, inhibition results. Thus it will be seen that in the vibratory stroke mechanically produced we may get (1) stimulation; (2) sedation; (3) inhibition, depending upon its length, force and the duration of its application.

Having briefly seen what mechanical vibratory stimulation is, the second and next inquiry in this consideration is as to *how* it can be most effectively applied.

(1) As to the stroke. Whether it should be a long or a short one depends upon the depth of the location of the nerve to which the vibrating stimulus is sought to be applied. The deeper the nerve or nerve center, the greater the intensity of the physical abnormality and the more remote its location from the spinal center, the longer, proportionately, should be the stroke. Superficially located nerves or nerve areas are better treated by a short stroke; and for delicate structures like the eyeball, the short stroke should always be used. It ought constantly to be remembered that the *length of the stroke* is always of greater importance than the rapidity of the vibrations.

(2) *The treatment should be localized.* If treatment is beneficial when applied to diseased or abnormally functionating organs or their neural connections, it is illogical, to say the least, to apply it to those parts that are not so affected. The general "shake-up" of the entire organism, such as some vibration instruments are constructed to give, is neither desirable nor productive of beneficial results. Those parts alone concerned in the diseased process should be treated.

(3) Treatment should usually be applied between the transverse processes of the spinal vertebræ which are immediately over the posterior division of the spinal nerves that control directly or reflexly the nutrition of the diseased viscera or area. In some instances, as in certain conditions of the liver, for example, the vagi may require treatment, but ordinarily it should be applied, according to Bayliss and Starling (see Kirke's Physiology, page 512), to the transverse processes from the third to the eleventh dorsal inclusive. For further example, the kidneys are stimulated from the eleventh and twelfth dorsal and first lumbar. Additional information in detail respecting the spinal nerve centers influencing or controlling the various viscera may be found in Kirke's, Foster's, Landois and Sterling, the American Textbook and others of the more modern works on physi-

ology. A medium stroke, and moderately deep pressure between the processes, should be used in treating the spinal nerves. The impulse thus set up is, it is believed, conveyed towards the cord, and is communicated at the juncture of the anterior and posterior roots in the intervertebral foramen to the anterior division of the spinal nerves, and through the *rami communicantes* to the sympathetic nerves lying on the heads of the ribs.

In stimulating the lymphatics, vibration should be applied to them direct. Similarly in the case of muscular contractures. By far the greatest benefit from this treatment will be realized through its application to the spinal and sympathetic nerves or nerve centers concerned in and controlling the affected organ, and which are reached mainly through the spinal cord.

In concluding this branch of the subject, it should be remarked that every mechanical vibratory instrument, in order to produce the best possible results, ought to be susceptible of and combine three distinct features:

(1) *Easy adjustment or change of stroke;*

(2) *The localization of the treatment at a given point; and*

(3) *Absolute rigidity of action*, by which is meant that the vibrations excited by the motor should be concentrated in the vibrating attachment and so introduced into the patient's body. In many instruments, *especially those having flexible shafts*, no provision whatever is made for this, and much of the vibration produced by the motor passes either into the hands of the operator or into the floor or base upon which the instrument happens to rest. Whatever other features a vibrator may advantageously possess, those above indicated are believed to be absolutely essential to the highest success. An inefficient instrument is not cheap at any price; and here as elsewhere, the best will, in the end, be found to be the cheapest, regardless of the relative price as measured by a money standard.

We are thus naturally led up to the third inquiry of our consideration, namely: What is this mechanical stroke, or the vibrations to which it gives rise, capable of accomplishing when applied to the human body? Its effects may be *stimulative*, *sedative* or *inhibitory*.

STIMULATIVE.

(1) When applied as a stimulant to the vasomotor areas in the spine supplying particular organs, the volume and flow of blood to those viscera are thereby greatly increased.

(2) Nutritive processes are consequently improved.

(3) Secretion and excretion are also improved; elimination, the great desideratum in so many diseased conditions of the body, is also increased.

(4) Muscular and general systemic metabolism is enhanced, with greater oxidation and the production of more animal heat.

(5) Improvement in the respiratory function. (Foster, in his Textbook of Physiology, page 370, has shown the existence of a nervous center of respiration which can be reached and *stimulated through the spinal cord.*)

SEDATIVE.

Its sedative effects are marked in cases of general nervous irritability, excitability, fatigue and, very markedly, in insomnia.

INHIBITORY.

The inhibitory power of the mechanical vibratory stroke is demonstrated in the prompt relief of pain and in the dispersion of congestions or engorgements.

The foregoing enumerated effects follow (in varying degrees, of course) from the application of vibratory stimulation to the nerves of the spinal and sympathetic systems. There yet remain to be stated two of the most important physiological results that follow the application of mechanical vibration, which alone would entitle it to a high and important place in physical therapy. These are:

(1) The relief or relaxation of muscular contractures.

In such cases vibration is applied deeply to the affected muscle as well as to its spinal connections. This is done in order to directly excite or stimulate the independent nerve centers, which inhere in all muscular structure.

(2) The removal through stimulation of the lymphatics and their glands, of many forms of tumors, enlargements, exudates and other products of inflammation; also the relief of varicosities and the dispersion of many varieties of cutaneous eruption.

In the treatment of a considerable number of cases of goiter, embracing all varieties, mechanical vibration may fairly be said to have been thus far highly successful either in effecting their removal absolutely or in greatly reducing their size.

From the foregoing epitomized statement of what this therapeutic agent is capable of accomplishing, it will be observed that its range of application is very extensive and comprehensive. There is no specialty in the practice of medicine in which it may not frequently be utilized with signal advantage. For the ophthalmologist in the treatment of anemic or hyperemic conditions internally or externally, and the gynecologist in dealing with non-suppurative pelvic congestion of various kinds, as well as for all the other specialists standing intermediate to them, this therapy possesses advantages of incalculable value.

Mechanical vibration is not claimed to be a panacea, gentlemen, for all human ills. Neither is it recommended as an *exclusive* system of treatment. It is not contended that all the results above enumerated will certainly and absolutely follow its correct application to every properly selected case. It does not aspire to accomplish the indefinite postponement of senile degeneration or to abolish the process of death of the physical body.

But, gentlemen, after having critically employed it almost daily for the past eight months in clinical work,[2] which embraced all phases of diseased bodily conditions, and in large numbers, I have now to say that I know of no other *single physical agent* that will accomplish as many of the above epitomized results, or as often and with as few failures, as that concerning which I have had the honor and pleasure of speaking to you to-night.

Medical Progress.

RECENT PROGRESS IN GASTRO-INTESTINAL DISEASES.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

DIAGNOSIS OF GASTRIC CANCER.

SALOMON [1] suggests a new clinical test. This is based on the supposition that the cancer discharges a serum containing nitrogen. The patient receives liquids — milk and gruels — in the morning; from two o'clock on, a diet which is liquid but also free from albumen — bouillon, coffee, wine, tea. At nine in the evening the stomach is thoroughly washed and nothing is allowed the patient during the night. On the following morning 400 cc. of physiological salt solution are allowed to flow into the stomach, then are withdrawn, and the procedure repeated until the surface of the stomach has been thoroughly washed off. The fluid thus obtained is tested for nitrogen by the Kjehldahl method and for albumen with Esbach's test. In the majority of instances — nervous dyspepsia, chronic gastric catarrh, gastroptosis, etc. — Salomon found that the wash water gave no reaction with Esbach's reagent or only a slight opalescence. The quantity of nitrogen varied between 0 and 16 mg. nitrogen in 100 cc. of the wash water. In all cases of gastric cancer which Salomon investigated the wash water showed an intense cloudiness, quickly becoming flocculent, with Esbach's reagent. The quantity of albumen by the Esbach method lay between $\frac{1}{10}$ and $\frac{1}{4}$%. The nitrogen was also correspondingly greater, ranging between 10 and 70 mg. per 100 cc. wash water.

THE DIRECT PERCUSSION OF THE EPIGASTRIUM AS A DIAGNOSTIC SIGN OF ULCER OF THE STOMACH.

Mendel [2] calls attention to the intense pain which ulcer patients feel from the lightest percussion in the epigastrium. Such pains are apt to persist after the completion of percussion. If the outermost points of these painful zones are connected a picture of the gastric ulcer will be projected upon the abdominal wall. The pain disappears with convalescence. Likewise in duodenal ulcer there is a sharply circumscribed painful area which can be demonstrated by this method of examination. This lies alongside the linea alba just below the center of a line drawn from the costal margin to the navel. This area is a little larger than a silver quarter of a dollar and disappears as the ulcer heals.

PERMEABILITY OF THE GASTRO-INTESTINAL WALLS OF CHILDREN FOR TUBERCLE BACILLI.

Disse [3] has studied the question of the permeability of the gastro-intestinal tract in young animals. He refers to the work of Römer, who showed that young colts will absorb tetanus and diphtheria antitoxins from the gastro-intestinal tract and store them up in the blood, but that they lose this power when they become three weeks old. Young rabbits react similarly. Such observations make it probable that there is some change in the epithelium of the gastro-intestinal tract as the animal grows older, and in fact this is the case. The mucus formed at birth in the epithelial cells of the stomach is small in quantity, but this increases rapidly in the first few days of life and soon approximates that of the adult. The intestinal mucous membrane of newborn animals, on the other hand, resembles that of the adult animal. V. Behring has called especial attention to the danger of infection in young animals from this lack of a mucous coating in the stomach.

Professor Disse was able to demonstrate the passage of tubercle bacilli as well as antitoxins through the gastro-intestinal tract of newborn mammals. His especial attention, however, was directed to the formation of the mucous layer in the stomach. In the adult the epithelial cells lining the stomach are divided into two layers — a basal, which is protoplasmic, granular and includes the nucleus; and a peripheral, which is homogeneous and extends to the surface and joins with that of the neighboring cells to form the mucous coating of the stomach. At birth there is also a mucous layer, but this is thin and not continuous. Before birth the cells do not show two layers, but are uniform throughout, except for a collection of granular material lying between the nucleus and the free surface of the cell. This granular material is thus wholly surrounded by the protoplasm of the cell. It takes the same stain as mucus and forms a sort of mucous plug in the cell. In the first few days of life the protoplasmic network which surrounds and separates the mucous plugs diminishes and each mucous plug spreads out until it reaches the periphery of the cell which encloses it and joins that of the neighboring cell. The coating of mucus thus formed gradually thickens, presumably requiring a longer time with large than with small animals to reach its full development. The period during which this coating is formed might be termed the critical period of the animal's existence — the time in which the animal is most liable to infection.

INSPECTION OF THE STOMACH.

Stockton [4] has very ably edited the translation of Riegel's "Diseases of the Stomach" in the

[3] Berl. klin. Wchnschr., 1903, No. 1, p. 4.
[4] Diseases of the Stomach, 1903. Riegel., p. 32.

Nothnagel series. The book is a masterpiece in itself and the American edition represents the best and latest work in this branch of medicine. The book is worth buying for the sake of Stockton's notes, a few of which we reprint. He inserts the following note on inspection:

"Inspection may be facilitated and the success of the method greatly enhanced by placing the patient upon a raised table, the head toward a window, the shades of which are so arranged that the light enters on a plane only slightly above that of the patient — the rays of light directed from the head toward the feet. Standing now toward the foot of the table, and bending from side to side, the examiner is able, by a little experience, to make out delicate shadows cast by the slight inequalities of the abdomen. These shadows are seen to move with respiration. By resorting to this method, the size, shape and position of the stomach can often be made out when ordinary methods of inspection are unsatisfactory. This maneuver is especially valuable in discovering the gastric and intestinal peristalsis, the presence of enlargements and, to some extent, the relations of the abdominal viscera. This method I have long practiced and can testify to its utility.

"Knapp has recently suggested this modification: 'With the patient placed in the position described, the observer stands at the side or at the shoulders, and brings his eyes down to the level of the abdomen, and carefully observes the respiratory waves passing over its surface. After a little experience one is able to detect delicate transverse lines or waves passing upward and downward with respiration. These lines are found to correspond with the curvatures of the stomach.'"

DEATH FROM INFLATION OF THE STOMACH WITH CARBONIC ACID GAS.

Stockton [5] reports the following:

"In the inflation of the stomach by carbonic acid gas there is an element of danger in case of ulcer, carcinoma or other disease that seriously weakens the gastric walls. It is true that accidents rarely occur, and yet caution should be practiced when the walls of the stomach are known to be diseased. Behrand and Hughes [6] report three fatal accidents resulting from the use of this method.

DANGERS IN THE USE OF STOMACH TUBES.

Stockton: [7]

"It would seem unnecessary to call attention to the dangers of using a cracked or otherwise weakened stomach tube; and yet the interesting case reported by Friedenwald [8] points out the danger of carelessness in this respect. The case was that of a colored woman, aged twenty, upon whom a quack doctor passed a defective stomach-tube, and in attempting to remove it left a portion behind. No evidence of the presence of the tube could be felt upon palpation through the abdominal wall. Upon entering the Providence Hospital, Baltimore, Dr. Harris performed a gastrotomy and removed two pieces of stomach tube, one 9¾ inches and the other 6¼ inches in length. The patient made an uninterrupted recovery."

Riegel [9] quotes a case reported long ago by Leube, but still worthy of repetition. The subject swallowed the whole tube. This was retained in the stomach for nine days, despite various efforts which were made to remove it. Finally there were "sudden nausea and a desire to cough, combined with a feeling of suffocation. The patient pushed her fingers down into the pharynx, found the sound behind the tongue and pulled it out with one jerk."

QUANTITATIVE ESTIMATION OF PEPSIN IN GASTRIC JUICE.

Many methods have been proposed in the last five years for the quantitative estimation of pepsin. These are an improvement on the simple test of the digestive action of the gastric juice, but are still unsatisfactory. The original test was performed by the addition of a small disc of coagulated white of egg to 5 cc. of the filtered gastric contents, adding, if necessary, sufficient hydrochloric acid to give a reaction for free HCl. The white of egg should be wholly digested or thoroughly disintegrated if left at body temperature for two to six hours.

Hammerschlag's method, [10] which was at one time in favor, has been superseded to a considerable extent by that of Mett. [11]

"It consists in sucking fresh egg-albumen into capillary tubes 1 or 2 mm. in diameter, coagulating the albumen by boiling, then cutting off portions, 3 to 5 cm. long, of the filled tubes, and adding these pieces of the tubes to gastric contents. The tube containing this is then kept at body temperature in the incubator for ten hours. At the end of this time each end of the tubes will show a lack of solid albumen, owing to its digestion, while in the central portion some will remain. Both the empty portions and the portion still full are carefully measured, and the activity of peptic digestion determined thereby. Borisson states that the relative amount of actual pepsin present varies according to the square of the length of the empty portion of the tube, the figures for the latter being expressed in millimeters, — that is, 3 mm. digestion equals 9 parts pepsin; 2 mm. equals 4 parts pepsin."

Mett's method in turn has been the subject of much criticism by Schorlemmer, [12] Nirenstein and Schiff [13] and Jung. [14]

Spriggs [15] bases a method for the estimation of pepsin on the fact that the viscosity of an albuminous solution decreases in the same proportion as coagulable substances disappear.

GASTRIC HYPERESTHESIA AND ITS MANAGEMENT.

Stockton [16] distinguishes the condition especially from hyperacidity. The examination of the gastric contents generally shows a diminished quantity of hydrochloric acid. Notwithstanding this fact, such patients generally feel better by the use of those means which diminish gastric acidity and prolong digestion and by the use of easily digestible substances.

CONGENITAL STENOSIS OF THE PYLORUS.

Graanboom [17] reports two cases of congenital stenosis of the pylorus. The first was a child two months old, who began to vomit, though never bile, when eight days old, and whose bowels moved only with laxatives and then but slightly. A cure was effected by washing out the stomach and diet. The stenosis, therefore, was simply a spasm. The second case, four months of age, had exactly the same symptoms, but did not yield to treatment. Operation showed a pylorus scarcely passable by a thin sound. Vomiting ceased after operation and the bowels moved naturally, yet the child died in six weeks. Autopsy revealed no reason for death. Pylorus was nearly ½ cm. thick. The writer collected eighteen cases of pure congenital pyloric stenosis. Laparotomy was performed in three instances, but in only one was it successful.

ACUTE DILATATION OF THE STOMACH.

Thompson [18] believes that a primary paralysis is the usual cause of acute dilatation of the stomach rather than an obstruction produced by the pressure of the superior mesenteric artery upon the duodenum. He shows that the situation at which the distended intestine passes into the collapsed portion is very variable. In a recently observed case the intestine was dilated for a distance of eight feet and nothing was found which could cause an obstruction.

ETIOLOGY OF GASTRIC ULCER.

Vedova [19] has produced ulcers of the stomach in fourteen dogs out of twenty-seven by resection of the celiac ganglion or of the splanchnic. The necroses, hemorrhages and ulcers were located near the pylorus in twelve of the fourteen cases and were in some instances accompanied with an excess of hydrochloric acid. The striking necrobiotic character of the microscopic appearances was noteworthy, as well as the relatively unimportant signs of reactive inflammation.

SUGAR IN THE DIET OF DYSPEPTICS.

Morgan [20] draws the following conclusions from the experiments he instituted to determine the effect of sugar on the gastric juice. Sugar in large quantities (90 gr. cane sugar, 180 gr. maple syrup) lowers the amount of hydrochloric acid and pepsin in the gastric juice of both healthy individuals and invalids. According to the results obtained in all cases, except those having achylia gastrica or chronic gastritis, it appears probable that by the addition or withdrawal of sugar the total acidity and free HCl of the gastric juice can be increased or diminished at will. The negative action of the sugar in achylic gastrica depends quite probably upon the atrophy of the mucous membrane; the unexpected increase of the gastric juice in chronic gastritis is perhaps due to the cleansing and even antiseptic action of the sugar.

HYPERACIDITY.

The above article of Morgan shows that sugar is suitable and should be useful in the dietetic treatment of excessive acidity of the gastric juice due to hydrochloric acid. It cannot be prescribed indiscriminately, but such patients usually are more comfortable when they take a cereal at breakfast and some are helped by the addition to this meal of honey or maple syrup. Fats and oils tend to diminish the secretion of HCl also, as Pawlow [21] has shown. Strauss and Aldor [22] demonstrated that fats are as well digested in hyperacidity as in subacidity. Thus by the administration of large quantities of sugar and fat to patients with hyperacidity we are instituting curative rather than palliative treatment and at the same time are building up the nutrition. Mild cases of hyperacidity are, as a rule, relieved by a glass of albumen water between meals. In severe cases, in addition to the use of cream and salads at the meals, it is often beneficial to prescribe a tablespoonful of olive oil in the forenoon, afternoon and on going to bed.

TREATMENT OF CHRONIC GASTRO-SUCCHORHEA.

Rollin [23] discusses this affection, fifteen cases having come under his care in the last sixteen months. He refers to the two classes of dietetic treatment — the administration of albuminous food in large quantities and frequently for the purpose of combining with the excess of acid secreted and thus rendering it harmless; and the other method, in which little albuminous food is given, in the endeavor by this means to stimulate as little as possible the gastric glands. The mild cases yield as a rule to either of these regulation methods of treatment. In certain severe cases of chronic gastric secretion in which the symptoms pointed to ulcer, Rollin has prescribed a rigid ulcer régime. The patient is fed only by rectal enemata for six to ten days, then gradually begins with the usual ulcer diet, but receives no meat until the end of eight or ten weeks. The symptoms cease and a cure results, as is proven by the examination of the fasting stomach.

HETEROCHYLIA.

Heterochylia is a name given by Hemmeter [24]

[16] Journ. Amer. Med. Assoc., 1902, Jan. 11.
[17] Cit. Arch. f. Verd., 1902, vol. viii, p. 671.
[18] Lancet, 1902, Aug. 2.

[24] Arch. f. Verd., 1902, vol. viii, p. 75.

to a suddenly changing state of gastric secretion which occurs chiefly in nervous dyspepsia. He found, for example, in the same patient and after the same test breakfast within one week normal acidity, hyperacidity and anacidity. Einhorn described a patient with absence of gastric juice for five years, at the end of which time hydrochloric acid reappeared. Similar cases have been reported by others in nervous diseases of the stomach. Boas has noticed changes in gastric secretion in organic disease of the stomach. Kuttner observed a decrease or even absence of hydrochloric acid during menstruation. Elsner found in some cases an increase, in others a decrease of hydrochloric acid. These various reports led Korn to collect the cases of heterochylia in nervous as well as organic diseases which have occurred in Boas' clinic. In six cases with the diagnosis neurosis and two of tabes dorsalis free hydrochloric acid was present at one time, but absent on another occasion. The same alternation was present in two cases of gastric ulcer and in a case of chronic gastritis, in which was an accompanying pulmonary tuberculosis.

These facts are of especial interest because they indicate what may be the explanation of those cases in which the symptoms of the patient fail to correspond with the results obtained from the examination of the gastric contents. They show the necessity of repeated examinations of the stomach, particularly in doubtful cases. When hydrochloric acid is absent and there is a suspicion of cancer, Korn emphasizes the suggestion of Boas to examine the contents with great care for blood and to test the motor function of the stomach, which, as a rule, early suffers in cancer.

SURGERY OF GASTRIC CANCER.

Petersen [35] reports the results of thirty cases of cancer of the stomach upon which resection was performed at the Heidelberg clinic. Twelve of the patients died soon after the operation; of the remaining eighteen seven are still alive. The resection in these cases was most thorough. Petersen's statistics show that life is prolonged in gastric cancer four or five months when gastroenterostomy is performed; six to eight months by the resection of the tumor.

INTESTINAL ANTIPERISTALSIS.

Grützner, in 1894, it will be remembered, called attention to the fact that small particles of charcoal or finely divided horse hair, when saturated with physiological salt solution and injected into the rectum, could be found six hours later throughout the small intestine and even in the stomach. In the same way starch would pass from the rectum to the stomach. Essential to this phenomenon in each instance was the presence of the salt solution. Ten years before Grützner's work, Nothnagel demonstrated active antiperistaltic movements of the intestine when salt was placed on the peritoneal coat. By these experiments Grützner and Riegel also concluded that nutrient enemata were similarly moved upward through the whole intestinal tract and thus were digested and absorbed.

Hemmeter [36] has investigated this question by a series of experiments upon four healthy individuals and in a cat and white rat. The stomach was shown first to be free from the substance — raw starch — which was chosen for the enema, and the diet was such as would not lead to confusion. Twenty-five grams of starch in 200 cc. physiological salt solution were then taken by enema at 9.30 P.M. On the following morning at seven starch was found in the stomach when it was washed with 250 cc. water. Similar results were obtained with charcoal, provided that like the starch it was suspended in the salt solution. This did not take place, however, if the starch and charcoal were suspended in weak solutions of potassium chloride or hydrochloric acid. Bismuth subnitrate and lycopodium also were similarly made to pass from the rectum to the stomach, and although suspension in physiological salt solution favored this it was not definitely proven to be absolutely necessary. Fasting favored the passage upwards of these enemata; constipation delayed it as well as diarrhea. The most favorable condition was presented when the bowels moved but once a day.

Peristalsis and antiperistalsis must therefore be going on simultaneously, since the bowels were moving daily during the experiments. Hemmeter explains this by considering that one set of movements (peristalsis) is central while antiperistalsis is peripheral. By experiments on cats he gained support for this hypothesis. By means of the x-ray the movement of subnitrate of bismuth could be watched from the rectum until it could be seen throughout the whole of the abdomen, and then it was demonstrated in the stomach by Savage. On killing the animal the bismuth was found to be situated peripherally in the small intestine. Hemmeter reaches the following conclusions:

(1) A movement of small particles takes place in human beings from the rectum to the stomach. This movement is favored by the suspension in physiological salt solution, is hindered or prevented entirely when solutions of potassium chloride or hydrochloric acid are used as a menstruum.

(2) The movement is marginal, because on sections through the intestine and on autopsies on human beings the particles are only found in the periphery and close to the epithelium of the intestinal mucosa.

(3) The passage upwards of particles to the stomach goes on simultaneously with the downward passage of fecal masses.

(4) This antiperistalsis cannot move the ingesta forwards *en masse* and for this reason cannot be considered an explanation for the digestion of nutrient enemata.

[35] Die Therapie der Gegenwart., July, 1903, p. 308.

[36] Arch. f. Verd., 1902, vol. viii, p. 59.

TREATMENT OF CHRONIC DIARRHEA WITH HYDROCHLORIC ACID.

Soufrault [27] and François [28] recommend the administration of hydrochloric acid in chronic diarrhea for the reason that this is due to a too hasty evacuation of the stomach. Different experimenters have shown that the food leaves the stomach more slowly in dogs, the greater the acidity of its contents. The assumption is therefore tenable that the presence of a large quantity of hydrochloric acid prolongs the stay of the food in the stomach and allows a more complete digestion. It does not appear that the acid improves the chemical work of the stomach, but rather reflexly excites the muscular fibers and produces a stronger contraction of the pylorus, which prevents the early passage of food into the intestine.

A CASE OF ULCERATIVE COLITIS CURED BY OPERATION.

Boas [29] advised operation in a case of severe ulcerative colitis which resisted all internal treatment. An artificial anus was produced at the cecum. The large intestine was then washed out with solutions of silver and iodine. The pus and blood gradually subsided and at the end of one year the fistula was closed. A fecal fistula remained for a few months. When this closed the cure was complete. The ulcerative process completely healed and only a mild constipation remained. A similar case was reported by Steiner at the German Surgical Association in Berlin, June, 1903.

Reports of Societies.

AMERICAN DERMATOLOGICAL ASSOCIATION.

TWENTY-SEVENTH ANNUAL MEETING, HELD AT WASHINGTON, D.C., MAY 12, 13, AND 14, 1903.

FIRST DAY, TUESDAY, MAY 12.

DR. JOHN T. BOWEN of Boston, President.

METHODS OF TEACHING DERMATOLOGY.

THIS was the title of the president's address. He stated that the didactic lecture, the clinical demonstration and the recitation all had their place in the teaching of dermatology. How much time should be accorded to each was a question about which there might be much difference of opinion and it would often have to be decided according to the resources of the department. He laid the most stress, however, upon the advantage of the method of teaching small sections of students from the patient or model and he believed that in the further development of that system lay most hope of improvement. The method required a large amount of material and a large force of instructors. With the development of section work instruction naturally became more complicated and more time was demanded of the instructors, so that the best teachers of the future would be obliged, perhaps, to sacrifice some of their private work. In the ideal dermatological department of the future it was to be hoped that the endowment would be sufficient to attract men of ability and enthusiasm to the chair, who would consider research and the teaching of their specialty their chief ends and who would be willing and able to subordinate their private practice to their vocation as teachers.

A CASE OF UNKNOWN INFECTION OF THE SKIN: POSSIBLY GLANDERS.

DR. J. A. FORDYCE of New York presented this communication. The patient was a man fifty-two years old, a native of Holland. His occupation was that of a cigar-maker. He was a very moderate drinker, but smoked heavily; he denied all venereal diseases. Five years ago he suffered from malaria and three years later from grippe and pneumonia; since then he had a slight cough at times and had lost some weight. He did not own a horse, nor had he handled horses recently, but he sometimes waited in a stable near the cigar factory if he arrived before the factory opened. He was admitted to the hospital March 11, 1903. Three weeks previous to that date, while removing ashes from the stove, he received a small scratch on the ring finger of the right hand. The wound became very painful and within a few days developed into a running sore. A few days later lesions developed on the upper lip, the right side of the mouth and on the head. When he entered the hospital he complained of weakness, chilly sensations, nervousness, headache and anorexia. The initial lesion on the ring-finger appeared as a deep, circular, fairly clean-cut ulcer, about the size of a cherry, without reddening of the surrounding skin or any evidence of cellulitis. It discharged a moderate amount of yellowish purulent material. There was a raised, irregular, confluent erosion of the skin of the upper lip, extending to the angle of the mouth and outward to the cheek for a distance of one inch. In the parietal and occipital regions of the scalp there were four large circular patches, one inch in diameter, with raised flat bases of dark brown color. Subsequently similar lesions appeared in the nose, mouth and throat, as well as on the scrotum and thigh, and death occurred on March 19, four weeks after the original infection. The autopsy, which was made by a coroner's physician, did not reveal any definite lesion to account for the man's death. The bacteriological findings were unsatisfactory, a growth of staphylococcus aureus only being obtained on the various media employed. Inoculations of guinea-pigs failed to give the characteristic reaction which was met with in glanders. Sections of the skin from the primary lesion and from secondary vesico-pustules showed the presence of an acute exudative inflammation, with evidence of hemolysis. Enormous numbers of staphylococci were present in the tissues. The infection undoubtedly occurred on the finger and rapidly spread by auto-inoculation to other parts of the skin and the mucous membranes. It dif-

[27] Cent. f. inn. Med., 1903, Feb. 7, p. 175.

[29] Deutsche med. Wchnschr., 1903, No. 11.

fered in its type from all the forms of infection produced by the staphylococcus or streptococcus. The negative results of the histological and bacteriological investigations left the cause of the process in doubt.

DR. HENRY W. STELWAGON of Philadelphia said the case appeared to him to be an example of one of those infections following vaccination or inoculation from an animal source.

DR. BOWEN thought the case bore a great resemblance to the acute form of pemphigus described by the French, occurring particularly in butchers and those who had to do with animal products.

DR. FORDYCE, in closing, said the case did not suggest a vaccination eruption. The lesions were very rapidly auto-inoculable.

RECENT CONTRIBUTIONS TO OUR KNOWLEDGE OF THE HYSTERICAL NEUROSES OF THE SKIN.

DR. A. VAN HARLINGEN of Philadelphia said that in a former paper, read before this Association in 1897, he reported several cases of erythematous eruptions in hysterical persons, which led to excoriations, or perhaps what might be called superficial gangrene. In a subsequent paper he attempted to collect and classify the various skin affections which had been reported as connected in some intimate manner with the pathology of hysteria. Although most of the hysterical neuroses of the skin were related to each other in their nature, yet it seemed more convenient to regard them as distinct and record them in connection with their dominant feature. Most hysterical skin affections appeared, at least at first, to be vasomotor in character. This fact had been noted by Bettmann, Perrin and other writers on the subject. Cases of hysterical gangrene showed certain characteristics common to all. The great majority, in fact nearly all of the cases, occurred in young females showing signs of hysteria, usually of a mild type. The affection frequently developed after some slight accident, a burn or some injury from a corrosive substance, a cut or a puncture. The first eruption commonly occurred at or in the immediate neighborhood of the injury, with considerable sensory irritation. A similar irritation usually introduced subsequent outbreaks. Sometimes the prodromata of gangrene were entirely absent; at other times the gangrene developed from an urticaria or erythema, or more frequently from pemphigoid blebs. Occasionally, a zosteriform eruption was the first symptom. When gangrene was established, the separation of the eschar often left an intractable ulcer terminating in a keloidal scar. While the extremities were the favorite sites of hysterical gangrene, the face and mammary region and other localities were sometimes involved, such as the external aural cavity and the mucous membranes. The question of self-infliction was of great importance in the study oft hese cases. In a few instances this had been verified and was traced to the usual causes of a desire to excite sympathy, to escape disagreeable tasks, etc., but a careful investigation into other cases failed to show the use of external applications.

RECURRENT BULLOUS DERMATITIS IN AN HYSTERICAL SUBJECT.

By DR. CHARLES J. WHITE of Boston. The patient was an American woman, twenty-three years old. She was distinctly hysterical and of a markedly neurotic and tuberculous parentage. During the past three years she had been the subject of a left-sided, recurrent, grouped, bullous dermatitis, which each year had attacked one part of the body and had, by repeated outbreaks, gradually advanced its position, each attack lasting about a week and leaving no mark behind. Dr. White said he regarded the case as an example of a rather extraordinary hysterical dermatosis. He did not see how that diagnosis could be avoided, for it seemed to him impossible to regard these one-sided, periodical, long-continued, progressive bullous outbreaks as due to the ingestion of drugs or to the infliction of self injuries and he knew of no cutaneous disease with such characteristics, outside of the mysterious dermatoses which we had learned to associate with hysteria. We could not place such an unusual group of symptoms under any of the well-recognized forms of disease, but must remain content to style it simply a cutaneous manifestation of hysteria.

DR. E. B. BRONSON of New York said that in studying these cases we should always bear in mind that in many hysterical patients there was a peculiar vulnerability or sensitiveness of the skin which was absent in the normal individual. There was no doubt that in many of these cases of dermatitis in hysterical subjects an element of deceit was present, but at the same time it took very slight provocation to produce very surprising effects.

DR. THOMAS C. GILCRIST of Baltimore said we were too apt to apply the term "neurotic" to an eruption that we could not classify or recognize its cause.

DR. F. J. SHEPHERD of Montreal said he had so frequently detected the practice of self-infliction in these cases that he was sceptical about the spontaneous origin of these gangrenous or bullous lesions. He agreed with Dr. Bronson, however, that there was a peculiar vulnerability of the skin of these patients.

Dr. WILLIAM A. PUSEY of Chicago said he was quite convinced that in certain cases of so-called hysteria we might get dermatoses that were not due to external irritation, but were dependent upon the hysterical condition.

DR. JAMES C. WHITE of Boston said he thought there was no doubt that even these deep-seated lesions of the skin, which we were prone to look upon as evidences of malingering, might occur spontaneously.

DR. VAN HARLINGEN said he had arrived at the conclusion that there were certain cases in which the eruption was the result of some internal cause and was not produced by the patient. All these cases belonged to the class of vasomotor disturbances, which embraced dermographism,

erythema, urticaria, bullous eruptions and hemorrhages from the skin.

SARCOMATOSIS CUTIS.

DR. G. W. WENDE of Buffalo reported this case. The patient was a colored woman, thirty-eight years old. The disease, resulting from an injury, made its appearance two years before her death in the form of tubercles accompanied by marked pigmentation and creating violent and persistent pain. One year later, when the lesions had attained a certain size, they broke down and this was followed by suppuration, exuberant granulations and free discharges. Microscopically, the skin tumors consisted of a round-cell infiltration, with scanty intercellular stroma. These formed nodules, chiefly in the hypoderm. The cells varied considerably in size. The disease hardly fell among those described as sarcomata, but should rather be classified, as Fuldt had suggested, among the granulomata.

FRAGILITAS CRINIUM.

DR. GEORGE T. JACKSON of New York reported two such cases. The first was in a young man of twenty-six; a clerk. The hair was thinned over the whole top of the head and was dry and lusterless. There was no sign of dandruff. The peculiar feature of the case was that there was a patch on the left side of the head, another on the right side and a third over the forehead, where the hair was short and curled up close to the scalp. These patches were sharply defined, like those of ringworm. There was no sign of inflammation. Under appropriate treatment, the patches disappeared within six months and the hair became normal in appearance. The second case was that of a lawyer, fifty-five years old, whose general health was good. His hair had been growing thin for some years. Four or five weeks ago he noticed, on combing his hair, that it was matted on the back of the head. Examination showed that on the top of the head there were two well-marked, rounded, sharply defined patches about the size of a silver dollar, in which the hair was short and apparently broken off. On the back of the head there was another patch in which the hair was broken off and curled close to the scalp, presenting an appearance similar to the curly hair of the negro. There were no signs of inflammation. The microscopical examination, made by Drs. E. Wende of Buffalo and Newborn of New York, disclosed no parasites, but showed many hairs with evidences of tricorrhexis nodosa.

AN UNUSUAL CASE OF TUBERCULOSIS CUTIS.

By DRS. T. C. GILCRIST and W. R. STOKES of Baltimore. The case was that of a colored girl who was first seen in 1894. She had cutaneous ulcerative lesions on the face, near the eye and on the nose. Sections from these lesions showed a fairly large number of apparently organized bodies, that is, they had a definite form and in some instances showed budding varieties. Most of them were situated in giant cells, but some were not. Tubercle bacilli could not be found in the tissue. Enlarged glands in the neck of the patient were removed and large numbers of similar bodies were found in them; the majority of these had undergone definite calcareous degeneration. A guinea-pig was first inoculated intraperitoneally and it died in a month. Small nodules were found in the liver. These nodules contained a large number of bodies similar to those found in the glands and skin lesion of the patient. The bodies were present in necrotic areas in the liver and there were many commencing pathogenic areas in which no bodies could be found. No tuberculosis was present in the guinea-pig. This experiment showed definitely that these bodies were not inanimate objects; otherwise, we would not get necrotic areas and such multiplication of these bodies. The death of the animal was apparently due to the presence and growth of these bodies. Further extended experiments with glands which were excised from the patient two years later did not lead to entirely definite results. Pathogenic lesions were produced in a dog and a number of guinea-pigs. In the dog, which was killed, bodies similar to those found in the patient were present in the enlarged cervical glands. A mould grew in another case and on potato a pathogenic streptococci was obtained. Nothing could be grown on any media direct from the lesions. The relapsed lesions five years later were undoubtedly tubercular, as shown by inoculation into a guinea-pig.

DR. M. B. HARTZELL of Philadelphia said the case was interesting, but he failed to see how Dr. Gilcrist had proved that it was one of tuberculosis. DR. STELWAGON agreed with Dr. Hartzell.

The PRESIDENT, DR. BOWEN, said that tissue which could not be differentiated histologically from that of tuberculosis had been shown to exist in so many different conditions that it was possible we had to deal here with a class of bodies which were perhaps degenerated elastic fibers or calcareous deposits.

[To be continued.]

Dwight's Epitome of Medical Jurisprudence. A Manual for Students and Practitioners. By E. W. DWIGHT, M.D., Instructor in Legal Medicine, Harvard University. In one 12mo volume of 249 pages. Lea's Series of Medical Epitomes. Philadelphia and New York: Lea Brothers & Co., Publishers. 1903.

This volume is one of a series intending ultimately to cover the entire field of medicine. It has been the editor's aim to provide brief manuals as contra-distinguished from mere compends. In the book before us this has been effected by amplifying the text to a certain extent and placing questions for students at the end of individual chapters. A very large number of subjects are briefly alluded to, and doubtful as we are of the ultimate value of such compendiums, we can easily see that many points of practical medico-legal interest are summarized in a way to render the book of value to students and practitioners not particularly engaged in this line of work.

THE BOSTON

Medical and Surgical Journal

THURSDAY, SEPTEMBER 10, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE LONG ISLAND HOSPITAL INVESTIGATION.

LAST week an investigation before a committee of the Aldermen and Councilmen of Boston into the management of the Long Island Almshouse and Hospital was closed after a duration of nearly eleven weeks, in which twenty-two hearings were held. The investigation was extraordinary in many respects, but especially from the fact that the charges brought against the Board of Trustees having control of the institutions were made by a certain member of that board, for motives which it does not concern us here to discuss.

For the benefit of those who may be uninformed it should be known that after various vicissitudes the institution on Long Island, about six years ago, was placed under a board of seven unpaid trustees, and thereby removed from immediate political control. Two years previous to this a visiting staff had been organized, in accordance with a recommendation of a former investigating committee. The general result has been the gradual development of a well-appointed and a well-conducted hospital for chronic disease, with the essential adjuncts of such a hospital, in the way of a training school for nurses, house officers, a pathological department under a salaried pathologist and the encouragement of teaching. The visiting staff and the Board of Trustees, with the exception of the one member to whom reference has been made, have worked with complete unanimity toward this end.

The details of the somewhat farcical investigation which has been made of the institution at the instigation of this one disgruntled member of the Board of Trustees have been so widely exploited in the daily press that no description of the proceedings is required here; certain probable effects of this investigation and the facts which it brought into public view are, however, of much more than passing interest to this community and to the cause of hospital care for the chronic sick in general.

In the minds of certain physicians of this city the feeling has long been gaining ground and the conviction strengthening that both for humanitarian and educational purposes the establishment of an adequate hospital for chronic disease is a necessity. This feeling has found expression in the progressive policy of the Long Island institution, encouraged by the visiting staff and made possible by the unfaltering co-operation of the Board of Trustees, as a body. The investigation just concluded has demonstrated this, and brought into public notice, as probably could have been done in no other way, the work which has thus far been accomplished in infusing a hospital spirit into an institution which previously did not rise above the level of an almshouse infirmary. We are firmly convinced that the city absolutely requires such a hospital in the fullest sense of the word, an opinion shared by the testimony of the various physicians called as witnesses. Regarding the situation from a broadly humanitarian standpoint, we fail to see wherein the opponents of this policy gained a single point.

The keen appreciation on the part of the majority of the Board of Trustees, of the medical needs of the city, as exemplified by this institution, is worthy of special comment, and this in spite of the fact that but one of the board is a physician. Had the closing argument in the investigation by Mrs. Alice N. Lincoln, as chairman of the Board of Trustees, come from the pen of a physician it could not more clearly have expressed the aims of the medical men who have been identified with the development of the hospital idea. It was at once a vindication of the policy of the trustees and a brilliant analysis and summary of the work of the past, the needs of the present and the hope of the future. In closing her argument, Mrs. Lincoln said:

> We have told you, without exception, that the welfare of that institution is inseparably bound up with the welfare of the humblest patient who is in its charge — that the adjuncts of a hospital, which have been complained of as too costly, are really one and all for the benefit of those persons who come there for treatment, and also for the benefit of humanity at large.
>
> Why is there a training school except to care for the sick; why is there a laboratory except to study the conditions of disease and health; why are there classes of stu-

dents except to show where future study and research may aid in preventing such ills as those from which these unfortunate people are suffering? The good of the patients is the first object of a hospital, but any hospital has also an important function to fulfill toward society in extending the scientific knowledge and treatment of disease, and affording facilities for its cure.

Whatever may be the result of this investigation, and that it will have some result I am reasonably certain, it is to be expected that the public will know better than ever before what is the scope and purpose of the Long Island institution, and especially of the importance of the hospital, which, although planned and built under our predecessors, has been developed and enlarged under the present administration along precisely the lines which, as already stated, were recommended by a previous investigating committee of the city government, and which, we believe, have received the indorsement of the citizens of Boston, both rich and poor.

With these statements we are in complete accord, and it is hardly to be expected that the better judgment of the people at large, to whom the final appeal must be made, will be other than favorable toward a policy which appeals at once to our sympathy, our reason and our common sense.

AS OTHERS SEE US.

IT is apparent to any one who observes, that not only are foreigners coming among us more often for purposes of observation as well as travel, but also that their opinions of American manners and customs are finding more frequent expression in print. This is true of medicine as of other branches of knowledge. Within this year two papers have appeared in foreign journals by physicians who have recently visited America.

The first of these, by Dr. Georges Guillain of Paris, was published in the *Semaine Médicale* early this year, and concerned itself particularly with the question of instruction in neurology in the United States. Dr. Guillain made a tour of the country, including San Francisco, and wrote on his return to Paris a readable and for the most part appreciative and correct estimate of the situation in that branch of medicine in America at the present time.

More recently an excellent exposition of American methods has appeared from the pen of Prof. C. A. Ewald of Berlin in the *Berliner Klinische Wochenschrift*. As is generally known, Professor Ewald came to this country by invitation to attend the meetings of the American Medical Association and the Association of American Physicians and Surgeons. In addition to attendance at these meetings, he visited various of the more important cities of the East, and has embodied his observations in a very entertaining and genial description.

In the first place, referring to the meetings he had attended, he remarks that it is apparently the English — meaning no doubt American — custom that papers are not given extemporaneously, but are read, which he regards as a less attractive method than extemporaneous delivery, and this he finds the more remarkable, since in discussion the writers prove themselves skilled and ready speakers. With this opinion we are in hearty agreement. If men would give the gist of their contributions without being bound to manuscript copy, the interest of hearers, as Professor Ewald suggests, would be very greatly enhanced. Of the "smoker" which formed part of the congress, the following comment is made:

Nur an einem Abend fand ein sogen. „Smoker" statt, ein zwangloses Beisammensein, bei welchem für deutsche Begriffe sehr mässige Quantitäten von Bier und einer Art Bowle aus Rothwein getrunken wurden.

In speaking of the papers read in the various sections, Professor Ewald alludes to the fact that nothing is more erroneous than the generally accepted opinion that American medicine is distinguished only in certain practical surgical matters and stands behind in other lines of research. While we have for a long time been conscious that this was the fact, it is nevertheless a certain gratification to hear such an expression of opinion from a man of such wide knowledge and keen perceptions as Professor Ewald. Were others as generous and as well supplied with knowledge of the actual facts, we have no doubt that the popular and undoubtedly existing cynicism of the Germans at large toward American medicine would quickly be set aside.

Dr. Councilman's contribution to the etiology of smallpox is regarded as one of the important matters presented to the congress, and the opinion is expressed that the question of artificial products or other mistake in the interpretation of the microscopic pictures is not to be thought of. A brief, comprehensive account of the whole smallpox question is given in this connection. The comments which follow on hospitals, training schools for nurses and methods of medical education are all interesting and worthy of a detailed reading. In hospital construction, a fact which apparently was impressive was the "*himmelstürmende Bauart*" of the buildings in New York City, the reason for which he rightly interprets as the increasing value of land, a fact which necessitates that

Die Häuser in schwindelnde Höhen hinaufzuthürmen, wenn man keine Luxusbauten machen will.

Many other matters, to which space does not permit us to allude, are contained in this thoroughly appreciative description of American medicine. Professor Ewald was most naturally entertained widely in various places which he visited, and gained thereby an idea of hospitality which possibly was not his before. We, on our part, were happy in having a man of such broad sympathies and wide professional culture in our midst, who was quite able to look beyond details to the broad methods and aims of the leaders of medicine in this country. A few such men visiting our shores would quickly bring about that cosmopolitanism in medical matters which has been too slow in coming, and which is altogether to be desired for the ultimate good and progress of medicine at large.

THE AMERICAN JOURNAL OF ORTHOPEDIC SURGERY.

A SPECIAL branch of medical practice may be regarded as firmly established when it has attained to the dignity of an exclusive publication. This process has been going on with increasing activity during the last few years. We have gradually seen journals devoted to specialized branches developing and taking a definite and apparently permanent place in medical literature. Publications devoted to ophthalmology, neurology, psychiatry, dermatology and other branches have all taken their places along with the recognized journals of medical progress. The latest to join the ranks is the *American Journal of Orthopedic Surgery*, the first number of the first volume of which is now in our hands. Orthopedic surgery and the general study of the subject of orthopedics has for many years been very active, and has brought much knowledge to other allied branches of medicine. Through the energy of the members of the American Orthopedic Association this journal now appears, to be published quarterly by the association, and to replace the Transactions of the association, Volume I of the journal being Volume XVI of the Transactions.

The editorial committee is composed of Dr. R. W. Lovett of Boston, Dr. D. E. McKenzie of Toronto and Dr. H. M. Sherman of San Francisco. The first number consists essentially of papers read at the recent meeting of the association in Washington. The first is by Louis A. Weigel of Rochester, who was this year president of the association, in which, rather opportunely in so special a journal as this, he discusses the question of the family physician, the specialist and the patient. Dr. Weigel is one of those who think that specialism should be a late development from the so-called general practitioner, and upholds his contention by various arguments, which it is not our present purpose to discuss. The names of Gibney, Bradford, Blanchard, Lovett, Goldthwait, Townsend and Whitman appear as contributors to this first number, a series of names so closely identified with the progress of orthopedic surgery in this country that the suggestiveness of their papers on various technical topics needs no mention.

Following the original papers a somewhat elaborate abstract department is appended which should be of the greatest possible service. Sceptical as we are of the attempt to abstract medical literature in weekly journals, we are quite convinced that such abstracts should form a most important part of a journal devoted to a special topic. In appearance this new journal offers little in the way of criticism. We note that the paper in general is rough and attractive to the eye, but that scattered through the text, wherever illustrations demand, an entirely different type of highly glazed paper is used in order that half-tones and x-ray pictures may be more clearly reproduced. This gives a somewhat uneven appearance to the pages as one turns them, and to our mind does not add to the attractiveness of the general appearance, necessary as it may be for the reproduction of cuts. On the whole we should much prefer the entire use of a glazed paper than this combination.

While we look with a certain regret upon the multiplication of periodicals, nevertheless we must be convinced that on the whole it conduces to the further development of medicine that each department which has attained to the rank of a so-called specialty should have its own journal. We have no doubt that this admirable publication, added to the long list, will find its place of usefulness and be an organ of importance to the growing number of votaries of orthopedic surgery.

MEDICAL NOTES.

CHICAGO THE VIRILE! — Under this heading the *Bulletin* of the Chicago Health Department makes the following statement: Of all the larger cities of the country Chicago has the largest proportion of males in its total population. During the last twenty years Chicago has averaged 5.3%

more males than females, while New York has averaged 2.8% more females than males, Philadelphia 5.7% and Boston 7% more females than males. Not only this, but Chicago's male deathrate is the lowest of the four cities — Chicago, 20.5 per thousand; Philadelphia, 22.9; Boston, 23.5; New York, 27.1, being the averages of the three Federal Census years 1880, 1890, 1900.

APPOINTMENT OF DR. WILLIAM A. WHITE. — Dr. William A. White, first assistant physician of the Binghamton State Hospital, has been appointed superintendent of the Government Insane Hospital at Washington in place of the late Dr. Alonzo B. Richardson. Dr. White is but thirty-three years old.

TRICHINOSIS IN HAMBURG. — A cable despatch from Berlin reports that in Hamburg and its vicinity two hundred persons are suffering from trichinosis.

CEREBRAL MORPHOLOGY. — The following statement is made in *American Medicine*: "The autopsy on the late Dr. Laborde of Paris disclosed an interesting fact regarding the brain. Dr. Laborde was an exceedingly fluent speaker, and it was desired to ascertain if the speech center was unusually developed. The left inferior frontal convolution was found to be much larger than the right. Its volume was the more remarkable because the brain as a whole was small, weighing 1,234 gm. (41 oz.) and the convolutions in general were but little complicated." Interesting as such observations are, we cannot but regard with scepticism the statement that fluency in speech should have so direct a bearing upon the cerebral speech area. Valuable as such apparently positive evidence may be, it needs very decidedly in matters of this sort to be controlled by a study of many brains, both of fluent and of poor speakers.

A SWEET GIRL MULTIGRADUATE. — The *British Medical Journal* thus characterizes a young woman of this city: "Miss Mary C. Lowell, M.D., of Boston, is said to be the only woman in the world who is entitled to practice the professions of medicine and law by virtue of the possession of degrees in those faculties. She was the first woman assistant superintendent of the Maine State Hospital for the Insane. After holding this position for five years she visited the hospitals of various European capitals. The love of study prompted her to elect a course in law, and it is said to be her intention to obtain two more degrees — Bachelor of Jurisprudence and Master in Chemistry."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Sept. 9, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 26, scarlatina 11, typhoid fever 34, measles 4, smallpox 0.

A CENTENARIAN. — Miss Larissa Shailer, the oldest spinster in Connecticut, died at Lyme, Sept. 6, at the reputed age of 103 years. Miss Shailer was born in Haddam, Sept. 21, 1800.

ENLARGEMENT OF STILLMAN INFIRMARY. — It is stated that Harvard University has purchased a very considerable amount of land adjacent to the Stillman Infirmary in Cambridge, and that owing to the demands made upon it by students of the university it has been decided by the trustees to enlarge the present building.

LIABILITY FOR BURNING OUT OF A FUSE. — A decision of considerable practical interest has recently been handed down by the full bench of the Supreme Court of Massachusetts relative to the question of liability of a street railway company operating electric cars for the burning out of a fuse. This decision was made in two cases, in which in the Superior Court damages had been awarded. The ruling of the lower court is, therefore, sustained. More in detail the court decides that the company is liable when the fuse burning out is in an imperfect condition. It furthermore decides that the burning out of a fuse is actionable when the fuse box is so situated as to be a source of danger to passengers. It is of some interest that practically at the same time that this decision was handed down an Italian in a neighboring town, frightened by the burning out of a fuse, jumped from a moving car and was killed.

NEW YORK.

HEALTH DEPARTMENT REPORTS. — The reports of the Health Department show an exceptionally low deathrate for this season of the year. During the month of August the mortality represented an annual deathrate of 17.28 as against 19.06 for July and 18.75 for August, 1902. The corrected deathrate, excluding non-residents and infants under one week old, was 16.49. Among the diseases which showed a reduction in mortality were the following: The weekly average of deaths from diphtheria and croup decreased from 36¾ in July to 24¾ in August; the weekly

average from scarlet fever, from 11¾ to 6½; from measles, from 15¾ to 5½; from pneumonia, from 58¾ to 51½; from broncho-pneumonia, from 47 to 32; from diarrheal diseases, from 301¼ to 257¾; from diarrheals under two years of age, from 277¾ to 225; from Bright's disease and nephritis, from 95¾ to 84½; and from organic heart diseases, from 78½ to 72½. Among the diseases which showed an increased mortality were the following: The weekly average of deaths from whooping-cough increased from 4 to 9; the weekly average from typhoid fever from 13¾ to 14¾; from acute bronchitis, from 13¾ to 16½; from pulmonary tuberculosis, from 125¼ to 145¾; and from cancer, from 50½ to 52¾.

From the condensed quarterly report of the Bureau of Records of the Health Department just issued, it appears that during the three months ending June 30, the second quarter of the year, there were in the city 16,674 deaths, which on an estimated population of 3,732,903 gives a deathrate of 17.93. Comparing this with an average number of deaths for the corresponding quarters of the preceding five years of 16,642 deaths, which on an estimated population of 3,448,567 gives a deathrate of 19.40 per thousand, it is seen that there has been a lowering of almost a point and a half. The deathrate of the following diseases shows a reduction: Measles, from 0.26 to 0.19; scarlet fever, from 0.34 to 0.29; pulmonary tuberculosis, from 2.34 to 2.14; pneumonia, from 2.76 to 2.60; diarrheal diseases, from 1.06 to 0.89; Bright's disease, from 1.52 to 1.49. In the following there has been an augmented deathrate: Diphtheria and croup, from 0.64 to 0.67; typhoid fever, from 0.11 to 0.13; cancer, from 0.67 to 0.69. It will be noted, however, that these increases are very slight, while several of the reductions are quite marked.

Miscellany.

INFANT MORTALITY IN NEW YORK.

WRITING in the *Medical News* on "Infant Mortality in New York," Dr. Rowland G. Freeman reaches the following conclusions: (1) The infant mortality of all countries is shockingly high, and this is shown to be unnecessary by the fact that infants that are well cared for show a very low mortality. (2) The influences that contribute to the high mortality are defective feeding, the active cause, and heat and humidity and bad surroundings as contributory causes. (3) There has been a marked decline in infant mortality during the last ten years in the United States and especially in New York City, due, for the most part, to the decline in mortality from summer diarrhea. (4) This is due to many agencies. The general adoption of pasteurization and sterilization of milk is the most important of these. Other agencies in New York City are the improved city administration, the milk inspection of the Department of Health, the Straus Milk Charity, the fresh air work of St. John's Guild and similar charities, cleaner streets and asphalt pavements, the new small parks, playgrounds and recreation piers, improved tenements and the use of antitoxin.

HYSTERICAL FEVER.

THE existence of a pyrexial condition in association with hysteria apart from any recognizable cause for the hyperthermia has been called in question, but there are a number of carefully made observations on record which seem to establish the fact of its occasional occurrence. It is claimed that the diagnosis may be made by noting the want of harmony between the temperature and the pulse rate and respiration. Moreover, in lieu of an increased excretion of urea, this "functional" fever is marked by a diminished, which is in accord with common experience; but how can the alarming increase of lunacy during the past fifty years be accounted for? — *Medical Press.*

NEWSPAPER MEDICINE.

THE following excerpts are taken from a single daily paper, and serve to account in a measure for the prevalent erroneous popular ideas regarding medical matters:

CHICAGO MAN'S HEART MENDED. — An operation was made on the heart of M. P., who was stabbed in a fight, to save the man's life. At Mercy Hospital, where he was taken, physicians took out his heart and sewed it up. Then oxygen was administered continuously, and it was said that he had a possible chance of recovery. The wound almost cut the man's heart in two.

DR. GARTNER OF VIENNA has just patented an instrument which records the pulse of a patient under the influence of an anesthetic. The instrument is fastened to the forearm and a graduated disc records the increase or retardation of the pulse. The experiments in the hospital of Vienna succeeded marvelously. It is hoped by means of it to prevent death during operations.

SURGERY FOR CONSUMPTION. — L G. of Hampton, N. H., underwent a rare surgical operation here on Saturday at the Stamford Hospital, as a last resort for the cure of pulmonary tuberculosis. An examination revealed a large cavity in the apex of the right lung and an abscess in the upper part of the middle lobe. The physician in charge of the case was satisfied that the only chance the patient had was an operation that would establish drainage through the chest wall. On Saturday, accordingly, he resected five inches of the second rib, four and one-half of the third and four inches of the fourth. The pleura being bound down by adhesions was brought into the wound and stitched there, both cavities were located and the pleura was opened with a needle. The cavities were thoroughly cleaned and drained with a rubber tissue drainage, and the wound was closed with the exception of space sufficient for drainage. The chest wall was strapped and dressed with a dry antiseptic dressing. A complete recovery is hoped for.

The optimism of the final statements in each of these instances is not calculated to instill correct physiological ideas into the popular mind.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUG. 29, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 3,342; under five years of age, 1,343; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 1,234, acute lung diseases 211, consumption 280, scarlet fever 21, whooping cough 30, cerebrospinal meningitis 12, smallpox 19, erysipelas 8, measles 9, typhoid fever 72, diarrheal diseases 652, diphtheria and croup 71.

From whooping cough, New York 8, Chicago 4, Philadelphia 5, Baltimore 3, Pittsburg 6, Lynn, Newton, Everett and Quincy 1 each. From erysipelas, New York 6, Chicago 1, Pittsburg 1. From smallpox, Chicago 2, Philadelphia 4, Pittsburg 13. From scarlet fever, New York 6, Chicago 5, Baltimore 4, Boston 1, Fall River 1, Lawrence 1, New Bedford 2, North Adams 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Aug. 15 the death-rate was 15.7. Deaths reported, 4,544; acute diseases of the respiratory organs (London) 120, whooping cough 63, diphtheria 59, measles 91, smallpox 5, scarlet fever 33.

The death-rate ranged from 6.9 in Reading to 28.9 in Birkenhead; London 14.2, West Ham 12.8, Brighton 10.8, Portsmouth 12.8, Southampton 12.3, Plymouth 15.8, Bristol 11.5, Birmingham 17.3, Leicester 14.0, Nottingham 14.4, Bolton 21.4, Manchester 20.7, Salford 21.6, Bradford 14.2, Leeds 18.9, Hull 20.1, Newcastle-on-Tyne 18.8, Cardiff 10.3, Rhondda 13.9, Liverpool 21.2, Burton-on-Trent 13.2, Bootle 27.5.

METEOROLOGICAL RECORD.

For the week ending Aug. 29, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

ERNEST F. ALEXANDER of Hoosick Falls, N. Y., a veterinary surgeon widely known in the section where he resided, died on Sept. 4, at the age of forty-two. He was a native of England and was a graduate of Toronto College, Canada.

THE death is reported at Herrinalb in the Würtemburg Black Forest, on Aug. 16, of DR. JOSEPH SCHNETTER, who was for forty years a practising physician in New York City. Dr. Schnetter was eighty-one years old. He was born at Gerdzheim, Bavaria, and was graduated with honors from the University of Würzburg. He came to this country in 1849, and later became one of the most distinguished and prominent German physicians in New York. There he was one of the founders of the German Hospital and Dispensary, which is now a large and flourishing institution. A few years ago he retired from practice on account of failing health and went back to Germany, where he has since resided in the city of Karlsruhe.

DR. EMILY R. ROBBINS, said to have been the first woman medical practitioner in America, has recently died in Philadelphia. She was born in that city seventy-one years ago and was graduated from a Pennsylvania medical school in 1857. Later she married a physician, and during the war rendered valuable services in caring for the wounded soldiers who were taken to hospitals in her native city.

BOOKS AND PAMPHLETS RECEIVED.

The Medical Epitome Series. Medical Jurisprudence. A Manual for Students and Practitioners. By Edwin Welles Dwight, M.D. Series edited by V. C. Pedersen, A.M., M.D. Philadelphia and New York: Lea Brothers & Co. 1903.

The Practical Medicine Series of Year Books, comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued Monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. VI. Chicago: The Year Book Publishers. May, 1903.

On Syphonage and Hydraulic Pressure in the Large Intestine with their bearing upon the treatment of Constipation, Appendicitis, etc. By Ralph Winnington Leftwich, M.D. Illustrated. New York: William Wood & Co. 1903.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Second Series. Vol. VIII. Washington: Government Printing Office, 1903.

A Reference Handbook of the Medical Sciences, embracing the entire range of Scientific and Practical Medicine and Allied Science. By various writers. A new edition, completely revised and rewritten. Edited by Albert H. Buck, M.D. Vol. VI. Illustrated. New York: William Wood & Co. 1903.

Tumours, Innocent and Malignant. Their Clinical Characters and Appropriate Treatment. By J. Bland-Sutton. Third Edition. Illustrated. Chicago: W. T. Keener & Co. 1903.

Organic Nervous Diseases. By M. Allen Starr, M.D., Ph.D., LL.D. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1903.

The Erotopath in Society. By Charles H. Hughes, M.D., of St. Louis, Mo.

THE ILL HEALTH OF FRANCIS PARKMAN.

BY GEORGE M. GOULD M.D., PHILADELPHIA, PA.

Boyhood. — Francis Parkman was born Sept. 16, 1823, in Boston, of the best New England ancestry. Farnham says that the tragic element in his life was probably as much the result of ignorance as of inherited weakness. As to "inherited weakness," one cannot inherit from ancestors what they have not, and there is not a hint that I have been able to discover which shows that Parkman's parents or grandparents had any of the physical troubles which made him suffer so grievously during his entire life. In his autobiographic letter he says of himself that his childhood was neither healthful nor buoyant, and that for a time though active he was not robust. Farnham says he had a delicate and sensitive physique, and was therefore sent at the age of eight to his grandfather's farm at Medford, Mass. Speaking of himself, Parkman says:

"I walked twice a day to a school of high but undeserved reputation, about a mile distant in the town of Medford. Here I learned very little, and spent the intervals of schooling more profitably in collecting eggs, insects and reptiles, trapping squirrels and woodchucks, and making persistent though rarely fortunate attempts to kill birds with arrows." Farnham adds that the woods, indeed, were so seductive as to be responsible for considerable truancy on his part, and some consequent fibbing. Those years at Medford were counted among his happiest, for the manifold interests and activities of country life were very congenial to his tastes.

"The causes of his early illnesses are enveloped in more or less mystery," says Farnham. "He was a headachy boy," Miss Parkman thinks,[1] and this illuminative remark, incidentally made, when coupled with the entire subsequent history of Parkman's life, hints at the key which unlocks the doors of the mystery. Boys of good stock and habits do not have headache except for good and sufficient reasons. When they live in the country and play truant, etc., as this boy did, the truancy is likely to be due to the unconscious desire to avoid headache. In such cases, as good oculists well known, the headache is most likely due to eyestrain. Reading thus between the lines, the oculist who remembers a large number of cases in his private practice of similar development in boys will also be struck by the likeness of essential psychologic conditions in the lives of the youth time of De Quincey and of Darwin. The erudite boy De Quincey was driven by the unconscious discomfort felt in study to years of vagrancy in the Welsh hills and elsewhere, and the intellectual son of intellectual parentage, Darwin, made his father despair by his addiction to "shooting, dogs, and rat catching." These and numerous instances in my practice have led me to formulate a rule as to the "truancy" and "play" and "athletics" of boys naturally intellectual, but who show a strangely illogic tendency to avoid all study of a severe or continuous kind. They will not and of course cannot explain it, but they will not read and study, and at once upon the application of spectacles correcting the ametropia which made study result in suffering or unconscious irritability, these "obstinate" and "wild" boys lead their classes and become men of learning or intellectual power.

[1] Personal communication. From the age of twelve (he being then twenty-one) his sister was his almost constant assistant and companion. (Since this was in type Miss Parkman tells me there is some doubt in her mind or in that of her sister as to the fact of headache in boyhood. It is not of much import. Boys with eyestrain usually avoid headache by avoiding reading and writing.)

"At the age of eleven or twelve," writes Parkman of himself, when he was forty-five, "he conceived a vehement liking for pursuits a devotion to which at that time of life far oftener indicates a bodily defect than a mental superiority. Chemical experiment was his favorite hobby, and he pursued it with a tenacious eagerness which well-guided would have led to an acquaintance with the rudiments of the science, but which in fact served little other purpose than injuring him by confinement, poisoning him with noxious gases, and occasionally scorching him with some ill-starred explosion." "Baneful to body and mind," he again pronounces this interest in chemistry.

During the years from thirteen to seventeen we infer that he was attending school in Boston at the Chauncy Hall School. We do not hear that he was studious, and all hints show that both before and after this he was far from being so.

The age of fifteen or sixteen produced a revolution. At that momentous period of life retorts and crucibles were forever discarded, and an activity somewhat excessive took the place of voluntary confinement. A new passion seized him, which, but half gratified, still holds its force. He became enamored of the woods, a fancy which soon gained full control over the course of the literary pursuits to which he was also addicted.

The college student. — He entered Harvard College in 1840. His biographer says he devoted himself with ardor to his special interests — the study of rhetoric and history, the pursuit of physical development and a knowledge of the American wilderness. How great, or rather, how little was his ardor for book study, may be gathered from the statement of his friend Mr. Wheelright concerning his social and student life at college:

He was very little in his own room, except at night for the purpose of sleeping. His constant craving for bodily exercise kept him out-of-doors or at the gymnasium the greater part of the day.

He now began, on entering Harvard, a course of physical training, by which he hoped to acquire the utmost strength, agility and endurance. . . . He took long walks at a pace his companions found it hard to keep up. . . . . One of his strongest characteristics, a love of stir and movement, pushed him to excessive activity. (Farnham.)

Parkman says of himself that he formed the plan of devoting himself to history-writing at the age of eighteen, and that to prepare himself "he entered upon a training tolerably well fitted to serve his purpose." One at first smiles at finishing this sentence describing this training — "slighted all college studies which could not promote it, and pursued with avidity such as had a bearing upon it, however indirect." Parkman himself continues:

His reliance, however, was less on books than on such personal experience as should in some sense identify him with his theme. His natural inclinations urged him in

the same direction, for his thoughts were always in the forests, whose features, not unmixed with softer images, possessed his waking and sleeping dreams, filling him with vague cravings impossible to satisfy. As fond of hardships as he was vain of enduring them, cherishing a sovereign scorn for every physical weakness or defect, deceived, moreover, by a rapid development of frame and sinews, which flattered him with the belief that discipline sufficiently unsparing would harden him into an athlete, he slighted the precautions of a more reasonable woodcraft, tired old foresters with long marches, stopped neither for heat nor rain, and slept on the earth without a blanket.

During his college course he spent his vacations in long trips to the wilds of New England, in 1841 to Portsmouth, Lake Winnepesaukee, Mt. Washington, etc., to the Androscoggin and Magalloway rivers. In 1842 a similar trip was made, and in 1843 one to Canada for historical materials, examining battlefields, etc. His physical condition and athletic powers were so well known that it was a surprise to his friends when in his junior year (1843) he gave up his studies and went to Europe "for his health." "Nothing," says Farnham, "very definite is known of the cause of this sudden change. Some think it was a trouble with his eyes, but there is no reference to this in his diaries and the few letters he wrote. It was probably, as others intimate, with apparently better knowledge, a trouble of the heart resulting from overstrain in the gymnasium at Harvard." [2] Parkman sailed in September and — a side light on the rigor of college courses and discipline at that time — he returned in time the next year to be present at the graduation exercises.

As a law student. — Graduated in 1844 by Harvard, he at once entered the Law School, and received the degree of Bachelor of Laws in 1846. He never entered the bar, and judging from the hints given we may suppose his teachers and examiners were as lenient as they had been in the classical department. Of this period Parkman says:

> "While following the prescribed courses at a quiet pace, I entered in earnest on two other courses, one of general history, the other of Indian history and ethnology, and at the same time studied diligently the models of English style, which various pursuits were far from excluding the pleasures of society."

When a student in the law school, he joined a class in riding under the instruction of a circus manager. With his chivalric and spirited temper he must have taken great pleasure in this knightly exercise. He chose the hardest horses, practiced riding in every form, with or without a saddle or stirrups; could run, leap, jump on a charger at full speed — in short, perform feats which only a "professional" could execute. In this study he probably had in view his "Oregon Trail" trip, which occurred soon after. If our athletic games had then been in vogue, his skill, courage, coolness and activity would have made him a successful competitor. (Farnham).

"The first trouble of which we have any definite knowledge," says Farnham, "was the beginning of an affection of the eyes." This extremely indefinite "definiteness" is further described as follows: "During his first year at the Law School, 1844–45, he rose very early and studied by candle light, often without a fire. In the course of the next winter, when confined to the house by some sickness, he, for the first time, pursued his studies by listening to reading." The journeys undertaken during his law course are epitomized by Farnham and show the fiery energy that drove him over so much of the country.[3]

"'*The Oregon Trail*,'" writes Farnham, "was undertaken partly to cure his eyes, partly to study Indian life." His friend Shaw and himself left St. Louis April 28, 1846, "on a tour of curiosity and amusement," quoting Parkman. In the preface of the book, written in 1872, he says:

> As regards the motives which sent us to the mountains, our liking for them would have sufficed; but, in my case, another incentive was added. I went in great measure as a student, to prepare for a literary undertaking of which the plan was already formed, but which from the force of inexorable circumstances, is still but half accomplished. It was this that prompted some proceedings on my part, which, without a fixed purpose in view might be charged with youthful rashness. My business was observation, and I was willing to pay dearly for the opportunity of exercising it.

At Fort Laramie he was taken down with dysentery, and says of himself in the "Oregon Trail":

> I had been slightly ill for several weeks, but on the third night after reaching Fort Laramie, a violent pain awoke me, and I found myself attacked by the same disorder that occasioned such heavy losses to the army on the Rio Grande. In a day and a half I was reduced to extreme weakness, so that I could not walk without pain and effort. Having within that time taken six grains of opium without the least beneficial effect,[4] and having no medical adviser, nor any choice of diet, I resolved to throw myself upon Providence for recovery, using without regard to the disorder any portion of strength that might remain to me. So on the 20th of June we set out from Fort Laramie. Though aided by the high bow "mountain saddle" I could scarcely keep my seat on horseback.

Another quotation from the "Oregon Trail" goes into further details of his condition:

> "At this time I was so reduced by illness that I could seldom walk without reeling like a drunken man, and when I rose from my seat upon the ground the landscape suddenly grew dim before my eyes, the trees and lodges seemed to sway to and fro, and the prairie to rise and fall like the swells of the ocean. . . . I tried repose and a very sparing diet. For a long time, with exemplary patience, I lounged about the camp, or at the utmost staggered over to the Indian village, and walked faint and dizzy among the lodges. It would not do; and I bethought me

[2] The gymnasium was established in his junior year.

[3] The vacations of the year he devoted to historical research. Taking his rifle, he tramped alone over the hills of western Massachusetts, to study the routes followed by the French and Indians in their attacks on that region. He passed through Springfield, Cabotville (old name of Chicopee), Chester Factory, Lee, Stockbridge, Great Barrington, Mount Washington, Lebanon Springs, Stephentown, the Hopper and North Adams.

The diary of 1845 shows that he had now focused his ambitions on a definite work —the "Conspiracy of Pontiac." In April of that year he made a trip to St. Louis and spent the summer in collecting materials for this volume. He visited Lancaster, Paradise, Harrisburg, Williamsport, Trout Run, Blossburg, Corning, Seneca Lake, Rochester, Buffalo, Detroit, Windsor, Sandwich, Mackinaw, Sault Ste. Maris, Palmer, Newport, Niagara, Oswego, Syracuse and Onondaga Castle. In all these journeys he showed indefatigable energy and alertness, and while his main interest was historical research, in which pursuit he noted the scenery of historic places, examined family papers and other documents and wherever it was possible interviewed descendants of the actors in his historic drama, his diary reveals almost as much of interest in nature, human nature and civilization. The sketches he contributed to the *Knickerbocker Magazine* show something of these tendencies crystallized in literary forms. In the winter of 1846 he made a trip through Pennsylvania, visiting Trenton, Philadelphia, Washington, Baltimore, Harrisburg, Carlisle, Chambersburg and Pittsburg. This year is marked also by his most adventurous and important expedition, the trip of the "Oregon Trail."

[4] This part of this sentence is oddly omitted in my copy of the "Oregon Trail," preface of 1872.

of starvation. During five days I sustained life on one small biscuit a day. At the end of that time I was weaker than before, but the disorder seemed shaken in its stronghold and very gradually I began to resume a less rigid diet."

He soon recovered and wrote that, "hardship and exposure had thriven with me wonderfully. I had gained both health and strength," and was "in high spirits." He had some relapses at a later date, but soon gained rapidly, ate well and went out hunting for sport, etc.

In his autobiographic letter, written years afterward, he speaks as follows of his life with the Indians:

> On a journey of a hundred miles over a country in parts of the roughest, he had gained rather than lost strength, while his horse was knocked up and his companion disconsolate with a painful cough.

The long and exhausting buffalo hunts toward the end of the trip, for the fun of the thing, and the homeward journey down the Arkansas Valley, show how strong and essentially unharmed he really was in health. Of another he wrote, "He was complaining that night of a disease the wasting effects of which upon a younger and stronger man, I myself had proved from severe experience." [5]

I have felt it necessary to quote so fully concerning the "Oregon Trail" trip, because Mr. Farnham, in ignorance of the real pathogenic condition, has in his comments put the matter in a wrong light. He says that "his mind at times lost its clearness." "The prolonged and excessive strain of the journey permanently impaired his digestion, thus reducing his powers to resist the development of disease. In this way the Oregon trip was the immediate cause of his infirmities, though some of them may have had their source in heredity." Farnham indeed suggests that his lifelong insomnia was due to this journey, and that "inflammation and weakness of the eyes naturally increased with the decline of his general health on the Oregon trip." Finally Farnham says that the "Oregon Trail" trip thus cost Parkman his health for life.

Farnham here repeats the same error as was exposed in a previous study of Darwin, concerning the effects of the Beagle voyage. As Darwin returned from the voyage unharmed, sound and healthy, so Parkman came home from the Oregon trip essentially without any permanent injury. His subsequent ill-health had nothing whatever to do with the hardships and temporary intestinal troubles of the outing among the Indians. "The sport," says Parkman, "was good, and the faith undoubting that to tame the devil, it is best to take him by the horns." The cause of all his succeeding illness (except of course the arthritis and rheumatism that came on later) was not suspected by himself or his biographer. This was eyestrain, which played no part during his Oregon journey, but which began its dominating influence at once upon his return to civilization, and made every day of his after life the supreme concern and every hour one of hidden suffering.

To the alertminded reader it will have become apparent that the school truancy, the interest in chemistry, the woods-roaming, the furious athleticism, the trip to Europe, the early choice of the peculiar historic subjects upon which to write — all were proofs only of a strange though unrecognized suffering when he wrote or read. The Oregon journey, itself preceded by the thousand-mile tramps and wanderings, were upon any other supposition strangely illogical. Parkman bravely convinced himself they were necessary to his preparation as a historical writer. But what a pitiable means to the end! It is plain that it was all but a powerful and subtle reaction against the ocular and cerebral injury wrought by the impossibility of visual labor with pen and type. There is, indeed, a large and hidden wisdom of the organism, a fused forefeeling and unconscious determination of the psychic and biologic personality which steadily and determinedly does the best it can with the condition at hand, the inherited tastes and abilities and the forelying circumstance or necessity of life. The youth and the entire life of Parkman, willed and potent as he was, is an illustration of how little the most dictatorial "environment" could conquer or long influence the more dominating temper of his character. Fate made him a true Yankee, and demanded his employment with intellectual and even with literary matters. It also gave him eyes that in any other man in the world would have rendered his living resultless to the world, and every hour a torture to himself. The torture he knew not how to escape, but he wrung from the bitterest suffering and the most unpitying fate great results for the world.

In spite of the fact that during his early years he was a wood-roamer, and even made commendable natural history collections, he was no scientist, and however ardently and arduously he prosecuted tree lore or animal study, or later chemistry, and still later horticulture, it is perfectly evident that his title rôle was not as scientist. He was cast by God for another part, and his soul's eye was set upon another ideal. He filled the small rôles as well as he could, but why he played them at all, and why he soon wearied of them, this is explained only by the fact that injury to eyes and the nervous system was unconsciously felt whenever he used his eyes in protracted reading and study. Hence he was driven to muscular activity, and being an intellectual man he could but choose the sole outlets for energy which united action and thought. The restless demon that from the depths of great men's souls ever cries out, *March, march!* begins his orders even

[5] Approaching St. Louis an incident occurred which must be quoted in full: " . . . Dr. Dobbs is there besides. I asked who Dr. Dobbs might be. 'One of our St. Louis doctors,' replied Tête Rouge. For two days past I had been severely attacked by the same disorder which had so greatly reduced my strength when at the mountains: at this time I was suffering not a little from pain and weakness. Tête Rouge in answer to my inquiries, declared that Dr. Dobbs was a physician of the first standing. Without at all believing him, I resolved to consult this eminent practitioner. He offered in his own person but indifferent evidence of his skill, for it was five months since I had seen so cadaverous a face. . . . I said I had come to ask professional advice.

"'Your system, sir, is in a disordered state,' said he, solemnly, after a short examination.

"I inquired what might be the particular species of disorder.

"'Evidently a disordered state of the liver,' replied the medical man; 'I will give you a prescription.' . . . He presented me with a folded paper. 'What is it?' said I. 'Calomel,' said the doctor.

"Under the circumstances I would have taken almost anything. There was not enough to do me much harm and it might possibly do good; so at camp that night I took the poison instead of supper.

in boyhood. In Parkman's case it was a very literal command, iron and uncompassionate. The order had been obeyed from early boyhood on, and by eighteen he found that he could "march" and be an intellectual and creative man at the same time, only by taking as his life work the peculiar kind of historical writing which demanded or seemed to demand many extensive journeys and original research not solely of a bookish kind. This decision and the theme of his work were of course consonant with the character of the man, but had it not been for his unrecognized although active ocular affliction, the peculiar choice would not have been made. This comes out in Parkman's graphic account of the conditions of his mind and life in which he speaks of the result of his strenuous efforts as culminating in

> A state of mental tension, habitual for several years, and abundantly mischievous in many respects. With a mind overstrained and a body overtasked, he was burning the candle at both ends . . . a pernicious intensity . . . a highly irritable organism spurred the writer to excess in a course which with one of different temperament would have produced a free and hardy development of such faculties and forces as he possessed. . . . Soon, however, he became conscious that the impelling force was growing beyond his control. Labor became a passion and rest intolerable, yet with a keen appetite for social enjoyment, in which he found not only a pleasure but in some sense repose, the stimulus rapidly increased. Despite of judgment and of will, his mind turned constantly towards remote objects of pursuit, and strained vehemently to attain them. The condition was that of a rider whose horse runs headlong, the bit between his teeth, or of a locomotive, built of indifferent material, under a head of steam too great for its strength, hissing at a score of crevices, yet rushing on with accelerating speed to the inevitable smash.

There is in these lines, as in everything written by Parkman about himself, a startling clearness of spiritual diagnosis, a truthfulness of view as to the facts and symptoms, and a most tragic failure to catch a glimpse of the pathologic condition that caused them. How near the eye came to seeing itself is shown by this swift glance:

> It was impossible that conditions of the nervous system, abnormal as it had been from infancy, should be without their effects on the mind, and some of these were of a nature highly to exasperate him. Unconscious of their character and origin, and ignorant that with time and confirmed health they would have disappeared, he had no other thought than that of crushing them by force, and accordingly applied himself to the work.

How little they did or could have "disappeared with time and confirmed health" we now know, and as his whole after-life proved, only science makes it possible for the eye to see itself.

Parkman's rigorous athleticism. — We have seen that Parkman seemed to be impelled to an extreme of athleticism by some illogical and half-unrecognized impulse. Farnham says of Parkman that

> His chief error was the not uncommon mistake of regarding exercise as the all-sufficient means of securing health. While developing his muscles he failed in the larger duty of acquiring a thorough knowledge of the laws of health. His physical culture had as close a connection with his personality as any other part of his education. His tastes and ruling traits pointed in advance to his course and the dangers he would be likely to meet. Early in his life muscular development became his hobby; he desired to equal the Indian in strength, agility, endurance and skill in woodcraft; he also became convinced that a healthy mind could exist only in a healthy body. But in pursuing these laudable aims he was exposed to many risks. His self-discipline began when he was yet a boy at home; he would not permit himself habits or thoughts tending in the least to weaken the central virtue of manliness. . . . Thus the ways of the prudent, complaining and self-indulgent invalid were to him worthy only of contempt. He himself, going to the other extreme, drove his body to exercise with an excessive and destructive ambition. He treated his infirmities by the fatal method of "crushing them by force," attaining almost a savage's endurance of pain. If the strongest mind, bent on attaining health and ignoring illness, were able to cure disease by will power, Parkman should have been the healthiest of men.

Concerning this aspect of his life, Parkman wrote of himself:

> But if a systematic and steady course of physical activity can show no better result, have not the advantages of such a course been overrated? In behalf of manhood and common sense, he would protest against such a conclusion; and if any pale student, glued to his desk here, seek an apology for a way of life whose natural fruit is that pallid and emasculate scholarship of which New England has had too many examples, it will be far better that this sketch had not been written. For the student there is, in its season, no better place than the saddle, and no better companion than the rifle or the oar. A highly irritable organism spurred the writer to excess in a course which, with one of different temperament, would have produced a free and hardy development of such faculties and forces as he possessed. Nor, even in the case in question, was the evil unmixed, since from the same source whence it issued came also the habit of mind and muscular vigor which saved him from a ruin absolute and irremediable.

In the words "a highly irritable organism spurred to excess," Parkman, with his usual precision, stated the facts without, of course, knowing the reason, or understanding why he had the "highly irritable organism." As an echo of this diagnosis Farnham again caught a glimpse of the truth when he wrote:

> His love of action always pulled against his love of study. Such seemingly incompatible passions are rarely seen together in such force. Even in his college days, while still in good health and much interested in physical culture, he was marked as a man of retirement and industry, a reserved, brooding student, who seldom invited any one to his room, and at the same time an impetuous, social youth. But action was his first instinctive mode of expression, his chief pleasure in life. And it was, moreover, a kind of abnormal, physical necessity, as well as a propensity of his mind.

More accurately and tersely Parkman's friend, Dr. George E. Ellis, saw the truth when he wrote that:

> His maladies intensified his impulses to exertion and mental application, while they limited the hours he could wisely give to reading and writing.

It is strange, as we now look back at the history, that none of his friends, not even the clear head of the patient himself, should have recognized the fact that the reflexes of eyestrain produced the "highly irritable organism" and pushed him to the furious physical activity which served at once to spare his eyes and to act as an outlet for the abnormal irritation engendered by

their use. He was accustomed to say, "I shall go to pieces if I do not exercise," or "I must exercise." [6]

On the gridiron and by means of the gridiron. — In 1846 Parkman returned to work, but found that only by the help of eyes other than his own could he do anything toward realizing his literary ideals. He dictated the "Oregon Trail," in the autumn, which was published in the *Knickerbocker Magazine* in 1847, and then took up "Pontiac." Farnham writes:

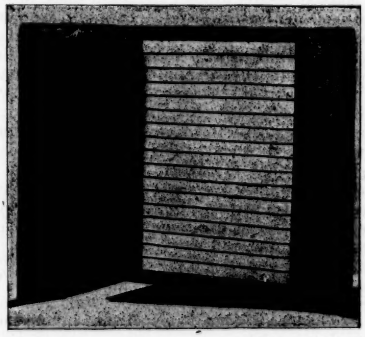
He devoted himself largely to medical treatment during 1847 and 1848. He spent the greater part of these years in New York and at West New Brighton on Staten Island, under the care of an oculist, also at a water cure in Brattleboro, Vt., to improve his general health. He returned to his father's house in 1849, having reaped but little benefit from the efforts of the doctors,— the "medical faculty," as he used to call them. With the help of his friend, Charles Eliot Norton, in reading proof, he was able to prepare "The Oregon Trail" for publication in book form.

In 1853 "the enemy" again became too aggressive to be ignored, and again he resorted to water cure at Northampton. He was always willing to give the doctors every facility and to undergo any method of treatment, following faithfully the advice he sought,— excepting in regard to giving up writing.

Meanwhile, with the help of his wife and her sister, Miss Mary Bigelow, as amanuensis, he pushed along his literary labors.

Speaking of himself in his autobiographic letter, Parkman says as regards his physical, mental and ocular symptoms, that in a few months after his return to the settlements he "found himself in a condition but ill adapted to support his theory." He continues:

To the maladies of the prairie succeeded a suite of exhausting disorders, so reducing him that circulation at the extremities ceased, the light of the sun became insupportable and a wild whirl possessed his brain, joined to a universal turmoil of the nervous system which put his philosophy to the sharpest test it had hitherto known. All collapsed, in short, but the tenacious strength of muscles hardened by long activity. This condition was progressive, and did not reach its height—or, to speak more fitly, its depth—until some eighteen months after his return. The prospect before him was by no means attractive, contrasting somewhat pointedly with his boyish fancy of a life of action and a death in battle. Indeed, the change from intense activity to flat stagnation, attended with an utter demolition of air castles, may claim a place not of the meanest in that legion of mental tortures which make the torments of the Inferno seem endurable. The desire was intense to return to the prairie and try a hair of the dog that bit him; but this kill or cure expedient was debarred by the certainty that a few days' exposure to the open sunlight would have destroyed his sight.



The autobiographic letter goes on:

In the spring of 1848, the condition indicated being then at its worst, the writer resolved to attempt the composition of the "History of the Conspiracy of Pontiac," of which the material had been for some time collected and the ground prepared. The difficulty was so near to the impossible that the line of distinction often disappeared, while medical prescience condemned the plan as a short road to dire calamities. His motive, however, was in part a sanitary one, growing out of a conviction that nothing could be more deadly to his bodily and mental health than the entire absence of a purpose and an object. The difficulties were threefold: an extreme weakness of sight, disabling him even from writing his name except with eyes closed; a condition of the brain prohibiting fixed attention except at occasional and brief intervals; and an exhaustion and total derangement of the nervous system, producing of necessity a mood of mind most unfavorable to effort. To be made with impunity, the attempt must be made with the most watchful caution.

He caused a wooden frame to be constructed of the size and shape of a sheet of letter paper. Stout wires were fixed horizontally across it, half an inch apart, and a movable back of thick pasteboard fitted behind them. The paper for writing was placed between the pasteboard and the wires, guided by which, and using a black lead crayon, he could write not illegibly with closed eyes.[7]

. . . . . .

He was at the time absent from home on Staten Island, where, and in the neighboring city of New York, he had friends who willingly offered their aid. It is needless to say to which half of humanity nearly all these kind assistants belonged. He chose for a beginning that part of the work which offered fewest difficulties and with the subject of which he was most familiar, namely, the siege of Detroit. The books and documents, already partially arranged, were procured from Boston, and read to him at such times as he could listen to them, the length of each reading never, without injury, much exceeding half an hour, and periods of several days frequently occurring during which he could not listen at all. Notes were made by him with closed eyes, and afterwards deciphered and read to him till he had mastered them. For the first half year, the rate of composition averaged about six lines a day. The portion of the book thus composed was afterwards partially rewritten.

PARKMAN'S GRIDIRON.
(From a photograph of the original instrument.)

His health improved under the process, and the remainder of the volume — in other words, nearly the whole of it — was composed in Boston, while pacing in the twilight of a large garret, the only exercise which the sensitive condition of his sight permitted him in an unclouded day while the sun was above the horizon. It was afterwards written down from dictation by relatives under the same roof, to whom he was also indebted for the preparatory readings. His progress was much less tedious than at the outset, and the history was complete in about two years and a half.

[6] Personal communication by his most kind and capable general physician, Dr. Oliver, who attended him for many years and to whom I am indebted for valuable and accurate information. When he could not walk, breathing and other sedentary exercises rowing, etc., were devised "to relieve the pressure."

[7] This, with the allusion in the second letter, is Parkman's only reference to this instrument, and his reticence as regards what seems to me one of the most heroic and pathetic experiences in history is profoundly touching. Miss Parkman has loaned me the "gridiron," and I reproduce here a photograph of it. The original I hope will be preserved in the archives of the Massachusetts Historical Society. A more precious relic will never come into their keeping.

(To be continued.)

MINOR SURGERY IN COUNTRY PRACTICE.[1]

BY CLIFFORD S. CHAPIN, M.D., GREAT BARRINGTON, MASS.

WHEN I was asked to write a paper to be read before the Surgical Section upon some surgical subject, I said to myself, I am not a surgeon, and what I may be able to write upon such a topic will be of little value. However, the thought came to me, how often a physician has to do minor surgical work; and with a little more care, and a little more knowledge, how much better work he could do. It is in village and country practice where a physician must be an all-round man, ready for emergencies of any nature, for often there is no hospital within twenty or thirty miles to which patients can be sent. To have to do this work is certainly excellent training for any one, but more especially for the young practitioner. If we do well the minor surgery, we will be more likely to work into, and do well, the major work which may fall later to the lot of some of us to do.

I have taken up for consideration some subjects which I feel are the more important ones of minor surgery with special reference to country practice.

Bandaging. — Bandages are employed to hold dressings in contact with the surface of the body, to make pressure, to hold splints in place in dislocations and fractures and to keep in place parts which have become displaced. The importance of being familiar with the rules of bandaging and to be proficient in applying the same cannot be overestimated. The general practitioner will never have cause to regret time occupied in learning to apply neatly this form of surgical dressing. A well-applied bandage adds to security of dressing and comfort of patient, and the manner in which it is applied often secures for the physician the confidence of patients and friends; while, on the other hand, a badly-applied bandage is uncomfortable and will cause adverse criticism to the doctor. It is not necessary to know how to put on every different kind of bandage, but to be well grounded in the principles of bandaging, and to have had a reasonable experience in applying same, is essential.

Asepsis and antisepsis. — Previous to Lister's method of treatment, it was the rule in accidental and operative wounds to have suppuration, fever, pain and often septicemia, erysipelas, etc.; hence the mortality was necessarily high. Mortality from compound fractures was very great, but by modern methods it has been reduced to a minimum. Lister's method was based largely upon the idea that the infection of a wound occurred from contact with the air, which contained spores and germs, and his method was to destroy them. It was later found that the germs from the air are usually of an innocuous character. Wound infection is more often from clothing, instruments, etc., which come in contact with it. It often depends upon the quantity of germs which enter, for we know bacteria may exist in an aseptic wound. It is well known that the same germ may produce different inflammatory affections. Some one has advanced the theory that all so-called pus diseases are simply local expressions of a general infection caused by many different micro-organisms. Acute suppuration is considered clinically to be always due to presence of bacteria, and their exclusion will prevent its occurrence. Asepsis aims at thorough sterilization of the field of operation and of all objects coming in contact with the wound, and the exclusion of micro-organisms by exclusive sterilized dressings. How important it is in all our work as physicians and surgeons to be very careful in attending to this in every detail! How much pain could be averted, how many amputations be prevented, and even major operations be saved, if only the physician who first saw the patient had simply done his duty and made the wound aseptic and continued to keep it so! It seems to me it is just here where so many of us fail. More often nature cares for the wound successfully, but even so it is our duty to always assist her when possible.

Antisepsis, on the other hand, has in view the destruction of micro-organisms by keeping germicidal agents constantly in contact with the wound. The object of antisepsis, therefore, is to produce asepsis. No one should undertake any operation or treat any wound without having clearly impressed upon his mind the importance of carrying out faithfully and scientifically all precautions necessary to prevent future infection of it. Since most wound complications are due to micro-organisms in it, it is the duty of the surgeon to prevent their entrance or employ means to destroy them. This must be done, however, without injury to the tissues of the body. Asepsis is always to be preferred to antisepsis when applicable. It seems to me so necessary that all practicing physicians should be well experienced in the ways of preparing patients for aseptic operations and caring for them afterwards. Usually these operations are performed in hospitals, but sometimes have to be done at the house. The surgeon perhaps is called from a distant city and has only a short time for operating. In hospital practice suitable rooms are provided for such work; in private practice, however, the physician is called upon to select a room and give directions as to its preparation. A well-lighted room should be selected and needless furniture removed. General directions which are usually given in textbooks seem to me to be in many cases impracticable. Often the room has to be gotten ready in too short a time to allow of removing carpets, etc., and if it is done, usually the dust created by so doing will be far greater than it would be simply to tack down upon the carpet sheets wrung out of bichloride. The great importance, in my judgment, is in paying due regard to asepsis of the wound itself. When possible prepare the patient the night before by bath, etc. The skin surrounding the site of operation should be thoroughly scrubbed with soap and water or a soup poultice applied for a few hours. Scrub the skin, not too roughly, then wash with alcohol and ether, then with sterilized water; afterwards a

[1] Read before The Massachusetts Medical Society, June 9, 1903.

dressing should be applied of either sterilized or bichloride gauze.

The instruments are best sterilized by boiling them for fifteen minutes in water to which a little washing soda (carbonate of soda) has been added. In treating infected wounds, abscesses, etc., some surgeons claim that free drainage is all that is necessary, but, in my opinion, the far better method is to treat the same antiseptically by using peroxide of hydrogen and washing with bichloride solution 1 in 2,000, and applying bichloride gauze.

Strapping. — How necessary it is to know how to do strapping and to do it well! Comparatively few country physicians pay much attention to it. If they do attempt it, it is usually done in the most crude and unfinished way. The plaster, of which I prefer the oxide of zinc adhesive plaster, can be gotten in narrow strips so that it can be neatly and evenly applied. I believe one of our best treatments for ulcer of the leg is strapping, yet I dare say but few physicians do it. In sprains it is our most useful treatment also.

Poultices. — Though poultices are used much less than formerly, they, however, do serve a good purpose at times. In inflammatory affections of the joints and of bones, when combined with rest their action is most satisfactory. In cases of deep suppuration, by their relaxing effect upon tissues they are useful and do not prevent the surgeon from using all aseptic precautions at time of operating.

Intravenous injection and infusion of saline solution. — It has been proved that normal salt solution will sustain the heart for a varying length of time as well as blood itself. Every physician should have an infusion set in his emergency bag and in his obstetric case, and should know how to use it. In profuse hemorrhage, severe cases of shock, septicemia and uremia it is invaluable. In puerperal eclampsia our best treatment, if the case will permit, is to do venesection and transfuse or infuse normal saline solution, until a sufficient quantity has been introduced into the circulation.

Anesthetics. — Anesthetics may be local, regional or general. Of the local anesthetics, the best are cocaine and chloride of ethyl. I have found the chloride of ethyl rather unsatisfactory; as to cocaine there is no question of its real efficacy, and as a rule the small percentages are as good and much safer, from a 1 to 2 % solution usually being strong enough for all practical purposes. Special care should be used when it is injected into the urethra, for frequently unpleasant effects are noted even when very small quantities of a 1 to 2% solution are used. Cocaine, when hypodermically administered, is very useful for operating upon fingers, toes and parts easily constricted; also for opening abscesses, removal of superficial tumors, etc. It is probably used for nose and throat operations more than in any other branch of surgery. A weak solution of supra-renal extract can be used in place of cocaine. Regional anesthesia I have had no experience with as yet. General anesthesia may be produced by administration of various anesthetics according to choice. Ether, however, is the more generally used. One of the most important things for a country physician, who is bound to meet and ought to be able to master all sorts of emergencies, is to know how to administer an anesthetic properly. I know when I was in the hospital, and undoubtedly it is so now, the most recent man on the staff always gave the anesthetic. I am glad now that the new man did give it, for if one is observant he learns a great deal by having to give it when there is an operator at work who will blame everything to him if anything goes wrong. I have often thought, when I have seen a physician trying to give ether and telling his patient at the very commencement to take long, deep breaths, that I would like to take the inhaler and crowd it over the doctor's face and make him take a few deep breaths. One has to take ether himself once to realize what that first feeling of strangulation is. It is unpleasant for any one to take, but it can be made comparatively easy by beginning rightly and having the patient breathe slowly at first, holding the inhaler at a distance, then gradually closer until anesthesia is complete, when it is astonishing how little ether will keep a patient profoundly unconscious. Every one should be aware of the possible accidents which may occur and be ready to do anything that may be necessary. I remember at one time, when I was an interne, seeing a young doctor giving ether, and suddenly a frightened expression appeared on his face — the patient's heart had stopped beating, his respiration had ceased; he was apparently dead. Various things were resorted to instantly without avail; finally the doctor said, "Damn it, why did you die on my hands?" and at the same moment struck the patient with his fist quite a severe blow directly over the heart. Almost instantly the heart began to beat and the patient to breathe and the apparently dead came to life.

I have never tried that treatment myself, as I have had no occasion to do so. No one should give an anesthetic without being ready with his hypodermic to give strychnin, atropin or digitalin as the case may need.

Treatment of hemorrhage. — It is very essential that a physician or surgeon should have a good knowledge of the anatomy of the blood vessels, that he may know at what points pressure applied will do the most good in controlling hemorrhage. The varieties of hemorrhage, arterial, venous or capillary, may be primary or secondary. Treatment should be both constitutional and local. Constitutional treatment consists in keeping the patient in a recumbent posture and avoiding any sudden change in position which might cause fatal syncope. I believe opium to be a valuable remedy in these severe cases. Some authorities think it is contraindicated on account of its raising blood pressure, but it is certainly useful where a patient is very nervous. Stimulants should be or should not be used as the exigency of the case demands. Infusion of normal saline solution should be resorted to when necessary. Local

treatment consists in using means, temporary or permanent, to control the bleeding. Digital pressure to parts, or to main artery, will control for the time arterial bleeding. A moderately tight compress will usually control hemorrhage until the parts can be sewed. Every physician ought to have in his emergency bag a tourniquet as well as hemostatic forceps for arresting hemorrhage. A tourniquet should not be allowed to remain for too long a time, lest paralysis or gangrene follow its use. It is when one is brought face to face with a severe post-partum hemorrhage that he wants to know all the various things for controlling it, but more than all he wants to know how to keep his head level and use intelligently and quickly the means he has at hand, or should have, in every case. There is one thing which I think is too often forgotten in these cases, which is quite sure to check it; that is compression of the abdominal aorta and keeping it compressed until uterine and vaginal tamponing has been done if necessary. In nose bleeding antipyrin in 5% solution has served me well when packing has not been resorted to. All arteries of any size should be ligated when possible. Secondary hemorrhages are much less frequent since the days of anti- and asepsis, but when occurring should be treated as primary.

Shock. — Shock is a condition of physical depression or prostration which may develop following severe injuries or operations. Feeble action of the heart and paralysis of the blood vessels cause an unequal distribution of the blood. Abdominal veins become distended, right side of the heart engorged and amount of blood in arteries correspondingly lessened. Brain and lungs become anemic. If this state continues, the action of the heart is stopped. The essential condition of shock is inhibition of nerve force and reflex paralysis. It may develop immediately after injury or later. The degree of it is usually proportionate to injury, but there are some exceptions, as contusion of viscera, etc., which though slight is often followed by grave or fatal shock. Burns and scalds, if they involve any considerable portion of the body, are apt to be followed by severe shock. I remember well cases of burns coming to the hospital in apparently good condition, and not an extensive surface burned, but dying within a few hours. In the treatment for this condition the first indication is to establish reaction. The patient should be kept very warm by being covered with blankets and surrounded with hot-water bottles, but using every precaution not to burn him. Foot of the bed should be raised and patient's head lowered. If he can swallow give whiskey, aromatic spirits of ammonia, by mouth, and strychnin hypodermically; when there is profuse sweating use atropin hypodermically also. An infusion of normal salt solution is to be used if necessary.

Fractures. — What an important subject to all, but especially to the country physician! I wonder how many of us younger men felt, when we graduated from college, that we knew well how to reduce and keep in place, in the best manner, the common, to say nothing of the uncommon, fractures. I had seen during my whole college course but few fractures and dislocations attended to. I had seen appendectomies, hysterectomies, etc., without number. No one was going to be willing I should perform any of these operations at the first, but I was likely to be called upon to reduce a fracture or relocate a dislocated bone at any time. I could put a bandage around it, go to my office and look up the different ways of dressing that particular fracture, go back to my patient and do the best I could; tell him he would probably have a deformity, but if nature did her work all right he would get a useful member. The colleges have heretofore been deficient in their real practical training in the very things which are so essential to the young physician in the beginning of his practice. Work improperly done at this time militates against him perhaps for a lifetime.

Operations. — There are certain operations which a physician should endeavor to familiarize himself with, for when the emergency arises to do them he must act promptly or his patient is promptly dead. I refer more especially to the operation for strangulated hernia. To be able to operate for this a good knowledge of the anatomy of the parts is essential. The physician must also have confidence in himself, and be able to inspire the same in others, and then must go ahead feeling that it is his duty to do the very best he can for his patient, under circumstances which will allow no wavering, and when prompt action will often be rewarded with a life saved and hesitancy be reproved with a life lost.

> "Call not on Hercules for help: his aid
> Ne'er serves the man who will not serve himself.
> Thine own arm must the conflict meet,
> Thy purpose being the victory."

In conclusion I wish to say that in our thirst for major surgery and the wonderful operations which stand pre-eminently as the great advancement in the science of medicine of the present age, let us not forget our duty as physicians and surgeons to attend well to the minor surgery which must necessarily enter into our daily work. Be well prepared so as to be ready at a moment's notice to attend to any ordinary kind of emergency which may arise. For minor surgery in country practice is no small part of a physician's work and is a part which tells for or against his reputation most markedly.

> "He who does the best his circumstances allow
> Does well, acts nobly: angels could do no more"

DISCUSSION.

DR. STEVENS of —— : After listening to this interesting paper I have very little to add. The reader seems to have covered the field, which is indeed a broad one. Speaking of bandaging and the avoidance of tight bandages — the hospital interne can see his dressings several times a day, but it is different with the country doctor. When he puts up a limb or does up a finger or hand it is

often left for twelve hours. It is well to bear in mind that it is going to swell at first probably.

As to the question of asepsis and antisepsis, rubber gloves to-day are a great help to us.

A word about bichloride tablets. It has been my misfortune in the last year to see two cases of poisoning by bichloride tablets. The country physician and surgeon often has to leave bichloride tablets at the house, and the utmost care should be taken with them.

I think that there is a great deal of value in formaldehyd solution, especially in pussy wounds, cases seen late, — 1 to 40 for maldehyd solution, a teaspoonful in a quart of water. It is pretty strong and smarts. It has a fine action on pus cavities.

Lysol is a valuable addition to our antiseptic surgery. I like creolin and moist bichloride poultices rather than the old-fashioned flaxseed poultice. Covered with paraffin paper the heat is retained.

I want to congratulate the speaker on his mentioning carrying the saline apparatus. We can get to-day our normal salt solution tablets made so as to dissolve them readily in boiled water. Representing the country physician and surgeon, I always carry a large bag. We don't know what we are going to until we get to the case.

Although a Harvard man, I like chloroform used in the proper cases. When a student I heard very little spoken about chloroform. It was always ether. I use more and more each year, but confining it to proper cases, especially young subjects with fractures. I like ethyl chloride. In short operations, like tapping the chest, I think you can anesthetize the skin so that there is very little pain.

It is well to examine the urine before giving any anesthetic. Another thing that presents itself to the country doctor, especially in manufacturing places: Cases are apt to come from the factories after a meal, and you have a great deal of trouble with the full stomach; things we never used to see in hospital work.

In the matter of hemorrhage I think there is one alkaloid of great value, and that is hydrastinine. I saw last year a case where there was oozing from all the mucous membranes apparently, and various things had been tried and hydrastinine controlled the bleeding. I do not think the patient was bled out, either.

If there is anything more troublesome than to be called to a bleeding tooth cavity in the night I don't know what it can be. Take 1 to 1,000 adrenalin solution on absorbent cotton and pack the cavity firmly and it will almost instantly stop the bleeding. It is said to be good in eye and nose work, as well as for hay-fever.

As to the question of shock, one thing struck me as important — care as to overdose, because absorption is slow after shock, the whole system is devitalized, the dose does not seem to act and you repeat and finally get overaction.

As to fractures, it is well not to be in too great a hurry to apply the permanent dressing. Reduce the fracture and wait for acute inflammation to subside. Placing an ice-bag I find is a great help. I believe strongly in plaster-of-Paris bandages properly applied.

If I am to operate I always try to have the room disinfected the night before. Formaldehyd comes in candles, and the room can be disinfected in that way. If time is limited I direct not to disturb things, such as pushing curtains up and cleaning off mantels.

DR. H. O. MARCY of Boston: There are said to be no minor things in life. The criticism I make on this admirable paper is the title — minor surgery. It is not minor in the slightest sense. It does us all good to review these fundamental principles of our work, and I am quite sure that we can all learn very much from such teaching. Personally, going over the history of a long life devoted to surgery, I now criticize my seniors rather than my juniors. In earlier days I was operating all over New England, and then ether was given by the family physician, usually little skilled as an etherizer. How few physicians to-day know how to give an anesthetic! I have often said I would give half the fee if I could have my etherizer. I believe faulty instruction in regard to etherization explains why ether is not given more outside of New England instead of chloroform. An impervious cone is usually used for administration. Nothing could be more faulty. Instead of a cone we should have a cylinder. Make the cylinder sufficiently open to carry the full volume of air the patient desires to breathe — air plus ether, and avoid asphyxia. Not long ago I had a good general practitioner give ether and came near losing the patient from his incompetency. He did not know that the patient must have plenty of oxygen with the ether. Such experiences, sometimes called minor, are the reasons why older men should review fundamental principles.

I criticize the injection of the peroxide of hydrogen into deep wounds. It is not so much of a disinfectant, destroying the bacteria, as we have sometimes thought, but an admirable means of disseminating them.

I find fault, also, with the late application of fixed plaster splints in dressing fractures. Put up a fracture as early as you may in a fixed apparatus. Reduction, retention, rest, not constriction, are the three R's of importance. The very first changes within the first few hours are processes of repair. What wounds shall we drain? Emphatically no wound that is aseptic. The primal exudation of leucocytes is of perfectly normal type, and is the "first aid to the wounded" if the wound is aseptic.

DR. D. H. CRAIG of Boston: The matter of rubber gloves was alluded to. The man who has to do the whole work, who has no assistant to help him in a country practice, oftentimes cannot properly sterilize his hands and get everything ready for an operation and maintain his hands in a sterile condition. If we have everything to work with the last thing to do would be to put sterile hands into sterile gloves. But we can carry a pair of sterilized gloves to the operation,

and these may be put on hands not perfectly sterile, if one has to do everything himself.

In the shock following severe traumatism the use of the adrenalin chloride in the dosage of ten to twenty minims of the 1 to 1000 solution properly diluted is perhaps one of the best in conjunction with strychnia and we have not the danger of cumulative action of strychnia after the first shock is over.

In relation to the use of anesthetics I had a point very forcibly brought to my mind recently which I think is not very generally known. In the use of chloroform or ether the sphincter muscles are the last to yield to the influence of the anesthetic. If the patient is in the condition of collapse, and you rapidly and forcibly stretch the sphincter ani, you almost invariably produce a gasp which will result in regular breathing following.

THE DIETARY TREATMENT OF CONSTIPATION.[1]

BY HENRY F. HEWES, M.D., BOSTON.

DURING my practice of medicine, in which through my hospital clinic and special branch of work I come in contact with large numbers of patients already under treatment at other hands, there is no fact which has impressed me more than the universality among the profession of the incorrect treatment of the condition of constipation.

To reinforce this statement let me take an extract from the records of my Out-patient Clinic at the Massachusetts General Hospital. In this clinic, out of a total of 1,200 cases seen during the months of July, August and September, 1902, 690, or 51%, gave a history of *habitual* constipation. Of these cases of habitual constipation, 660, or 90%, were using for this complaint a regular dosage of drugs which had been at some time prescribed for them, and had used drugs from the time of their first medical consultation on the subject, having received no other directions for treatment, excepting possibly that of a regular habit as to time of operation. Of the remaining 10% of cases a few had received general directions as to diet along with their drug prescriptions and the remainder were using no treatment at all.

A review of the records of my private practice shows a very similar set of results. In this practice, practically all the cases of constipation seen were using drugs for relief. About half these cases, as against 5% in the hospital cases, had received directions as to diet and habits in connection with their treatment. But in all cases drug treatment was associated with the diet and régime from the start, and there were no cases in which a pure dietary treatment had been instituted at the start or in which a systematic transition from a mixed drug and diet treatment to a pure dietary régime had been planned.

The result in both hospital and private cases was that in a great majority we had no real improvement in the underlying condition as the result of treatment, but on the contrary a much more fixed habit, both physical and mental, and a need for constantly increasing or changing drug dosage for temporary relief superimposed. All these cases have been treating for constipation for a year or more and in none had the necessity for drug dosage lessened.

Of course, there are physicians who prescribe diet and régime pure and simple for their cases of habitual constipation, and, of course, there are cases of constipation treated by drugs which, if the dosage and habits of the individual are carefully managed, are cured. And drugs may be useful for temporary conditions. But the general facts emphasized so clearly by these records quoted above — that the use of drug treatment with or without dietary or régime directions for *habitual constipation* is practically routine and universal in the profession and that such treatment is in a large per cent of the cases ineffective as regards cure — are undoubtedly true.

There is no necessity for me to dwell upon the fact with you that this condition of things is all wrong from the point of view of good medicine. The regular use of drugs to preserve the continuance of or to stimulate a physiological function is always a debatable measure and one which should be established or maintained only after a thorough search for and trial of more natural methods of relief. And this is particularly true where the weakened or disturbed function has become so, as is the rule in the condition of which we are treating, as a result of some faulty hygiene rather than through actual organic disease.

We wish to cure our patients, not to relieve them and certainly not to make them victims of drug habits. And when the patient shall pass from us to some other guardian we wish to leave as the result of our work not a harder but an easier task for our colleague.

The consideration of these facts, thus emphasized in practical experience, has led me to an extended study, partly experimental, of the subject of the treatment of constipation in general medicine, and it is the results of this study or of a part of it which I wish to present to you to-day.

The direct object of the study has been:

(1) To establish a method of determining as far as possible in a given case the source or underlying causes of the constipation present.

(2) To ascertain a method or methods of treatment of the condition in its various manifestations which will tend to establish the natural physiological function as far as possible as a permanent and self-supporting condition.

It is taken for granted in the study that the function is one which should go on in every individual independently of external artificial aids other than those which are always present in the natural course of hygienic existence, namely, the food, bodily exercise and a regular habit.

Where this regular physiological function is lacking, that, is in any case of constipation, we can assume that we are dealing with one of two general propositions. Either the patient has some definite pathological lesion or condition,— as some

[1] Read before The Massachusetts Medical Society, June 9, 1903.

obstruction to the intestine, some lesion of the nerve mechanism or its function, or some general disorder of metabolism which affects the normal action of the intestines, — or he is living under a faulty condition of hygiene, as a result of which the natural forces or stimulants of the physiological function are lacking. And our course in the study of our case is to determine in how far either of the above elements, the pathological or the physiological, is an underlying factor; and if the pathological, what its nature is, and then proceed directly to the removal or remedying of the cause or causes as the fundamental step in the treatment of the case.

Now acknowledging that a faulty hygiene, a lack of the natural agents or stimulants of physiological action, may be a cause and a total cause of constipation, — and this fact is proven beyond all doubt by extended research, very definitely also, as you will see, by the results of this investigation which I am presenting to you,— the proper plan of treatment in all cases is clearly, whether a definite pathological cause has been determined as an associate in our case or not, to effect at the start as far as possible a correct hygiene in this respect. If the faulty hygiene is the cause of the constipation, this measure will cure. And whatever our cause or causes may be, this step is in the right direction, as establishing at the start one correct factor of treatment and at the same time helping us to a diagnosis of the actual causal condition of our constipation by exclusion and assisting in the cure, whatever this further condition may turn out to be. If an underlying pathological condition is present and the constipation fails to yield to correct hygienic régime we can then proceed to the removal or remedying of this cause by further means.

And here again in our second step we must keep equally in mind the fact that we are working to establish a normal physiological function, which should go on of its own accord independently of artificial aids, and that whatever relief we may obtain by artificial means, as, for example, drug dosage, a cure can be said to have been established only when the function does go on unaided excepting by natural agents, as food and hygienic measures. That is, if besides removing or remedying a definite cause — as an obstruction, a weakness of innervation, or faulty metabolism, an anemic condition — by appropriate treatment, we find it necessary to stimulate or control the intestinal functional action of secretion or motion, we must do so as far as possible by the employment of those means, increased in degree but similar in kind, which nature uses for the purpose in hand; that is, by the supplementing natural hygienic agents to intestinal action, the inclusion of special foods and extra exercise in the régime. In this manner we depart as little as possible from the normal in the habits of the patient and of his economy, and make a final resumption of normal existence under the progressively improving conditions of health more easy to re-establish. Only as a last resort or for temporary use should we avail ourselves of the assistance of artificial stimulants, as cathartic drugs, which from the very nature of their action make a resumption of the normal habit more difficult.

The first step in the rational treatment of a case of habitual constipation is therefore often, regardless of what the associated pathological condition may be, the establishment of a normal hygiene, especially in regard to the function of intestinal action.

Experience has taught us that those factors of hygiene which bear most directly upon the physiological function of the intestine are:

(1) The habit of a regular period of defecation.
(2) A proper amount of physical exercise.
(3) A proper diet.

We must at the start, therefore, advise as to these.

Of these factors the first two explain themselves.

In regard to the third it is necessary first to ascertain the exact nature of the patient's accustomed diet and to supplement this until it corresponds to the normal diet.

The character of the normal diet, that best suited to the average individual and correct according to a scientific study of the body metabolism, is as follows[2]:

The quantity of a normal diet should average, under ordinary conditions, from 40 to 50 calories per kilogram of weight, or from 2,800 to 3,500 calories in twenty-four hours.

As regards quality, the best diet for all purposes in the average individual is one which approximates for every 100 calories of food 51 of carbohydrates, 29 of fats and 19 of proteids, or for a calorie value of 2,200, carbohydrates 1,100, fats 663, proteids 427. The normal diet should be made up also as much as possible of foods in their natural state, cooked or uncooked, and not of artificial preparations of nutritious principles; that is, meat, eggs, cereals, bread, vegetables, white and green, fruit, milk, — the kind of diet man in this zone has accustomed himself to for ages. (Vid. notes 4 and 5.) It should contain in addition to the food about three pints of water daily.

When we have established a diet for our patient approximating this normal standard we must next consider what further aid to nature can be obtained along these same simple lines.

The constipation in the case may be and frequently is simply due to the absence of the proper regimen. This faulty regimen long continued may have induced sluggish habits of the intestine, so that some additional stimulus to action besides the average normal is needed. Or we may be dealing with a condition of atony of the intestine, some weakness of the muscle of the wall or of its innervation, where some extra stimulus to action is necessary.

In seeking some aid for this stimulation we look most naturally to the food, which is the one of our normal hygienic factors affecting the intestine which can be most easily varied or reinforced; that is, we include in or add to our normal diet

[2] Rubner: Leyden's Handbuch der Ernährungs-Therapie. Bd. 1, 1897.

those articles of food which are known to be, among the general foods utilized, those which have most influence on the action of the bowels.

It is a well-recognized fact that in addition to the general action of the normal food products upon intestinal action, there are certain food elements which have a more special influence upon this action.

This marked influence of special foods upon intestinal action was first impressed on my mind as a definite scientifically-demonstrated fact by some observations of Westphalen.[3] This observer, in several years of practice in Russia, partly among peasants and partly among dwellers in St. Petersburg, noted the fact that while constipation was a very common affection among the citizens it was almost unknown among the peasants. The same distinction existed even where city dwellers of the same habits of exercise as the peasants were observed. In searching a cause for the fact observed, Westphalen located it in the diet of the two classes. That of the peasant in Russia consists almost entirely of vegetable food, including coarsely ground grains. That of the city dweller, as worked out in the writer's tables, is made up in much greater proportion of animal food and contains few coarse grains and much less vegetable matter. Taking these observations as a basis for his experiments, Westphalen tried placing patients with habitual constipation on the regular peasant diet, with marked substantiation of the original hypothesis deduced from his general observation, that the vegetable diet serves as a marked stimulus to intestinal action.

Starting, then, with this hypothesis, that the intestinal function may be greatly influenced by the quality of the food, we must in connection with our plan of treatment first study the special action of the various substances in this regard.

A thorough consideration of the various food substances from the point of view of their influence upon intestinal action indicates that the foods having this special action may be divided into three classes, according to their way of producing their influence.

In the first class we have all food substances possessing a large undigested or unabsorbed residue (even when taken in quantities so moderate as not to overtax the alimentary canal). These are principally vegetable substances possessing much cellulose, as the grains in coarse form, green vegetables, fruit, also foods with many seeds, as berries, figs, etc. It is this class of substances which predominated in the diet of the Russian peasants observed by Westphalen, and which was utilized by him in the treatment of constipation.[4]

[3] Westphalen treated 110 cases of habitual constipation of the type known as atonic constipation by dietary measures pure and simple, using an excessive vegetable diet, occasionally reinforced at the start by oil enemata. Of these 99 were cured without resort to drugs, 11 cases only necessitating the use of drugs, as cascara.—Westphalen: Archiv. f. Verdauungs-krankheiten, Bd. vi, p. 161.

[4] Rubner has shown experimentally that on a diet made up entirely of animal food, the intestines take three or four days to show the residue, while with a vegetable diet of corresponding nutritive value emptying occurs in from nineteen to twenty-four hours. On a diet of beets rich in *cellulose* (see table, page 537) emptying occurred in four hours. — Rubner, loc. cit.

While a fasting stool (observation on the faster Cetti) weighs about 20 gm. daily, a stool from an individual on an average normal diet of meat and vegetable and fat weighs from 100 to 250 gm. A stool from an individual upon a purely vegetable diet of equal nutritive value to the normal diet averages about 500 gm.—Hammeter, "Intestines," vol. I.

The quantity of unabsorbed or undigested residue obtained under ordinary conditions from common food substances can be seen from the following tables taken from Rubner (loc. cit.):

Food.	*Dry residue.*	*Per cent. Unabsorbed. Proteid residue.*	*Per cent. Unabsorbed. Carbohydrate residue.*
Meat	4.9	2–2.6	
Fish	4.3	2–2.5	
White of egg	5.2	2.6	
Milk	8.8	7.8	1
White bread	4.2	21	2.9
Rye bread	20.9	46	14
Pumpernickel	19	43	13
Rice	4.1	20	0.9
Peas	9	17	3.6
Beans	15–18	30	7.4
Potatoes	9	30	15
Crisp cabbage	14.9	18	15
Turnips	20.7	39	18
Beets	20	39	18

This table shows also the carbohydrate residue which may by undergoing fermentation form products which increase intestinal action. These cellulose substances have a further value besides their production of large residue. The cellulose forms material for fermentation in the intestine with formation of organic acids, which naturally aids intestinal action.

Another food substance which may serve to reduce residue in special cases of constipation is fat. As a rule the fat taken in normal quantity leaves little if any residue. If an excess is taken, however, a considerable residue may remain, which acts also as lubricant of the intestine. Thus Berthé[5] has shown that in a diet consisting of 350 gm. of meat, 500 gm. of bread and 60 gm. fat, 7 to 8% only of the fat appears in the feces. If to this diet 60 gm. of fat be added, the residue of fat begins to increase after an initial period of extra absorption, rising to 12 on the seventh day, 18 on the twelfth day, 49 on the thirtieth day. The use of fat to increase residue is not, however, quite so much in the purely physiological line as that of the cellulose vegetables first mentioned in this class, as these produce residue even when taken in ordinary amount.

The second class of food substances having special influence upon the intestinal action consists of foods containing considerable quantities of organic acids or other substances which by their local action, or their action upon metabolism or nerve centers after absorption, increase intestinal activity. In this class are certain fruits, especially the *tamarind*, *prune*, *plum*, *manna* and certain green vegetables.

The third class consists of substances which undergo fermentation in the intestine, with formation of organic acids. These are the carbohydrate foods generally, including the cellulose of the vegetables already mentioned.[6]

[5] Berthé, quoted by Maly, Hermann's Handbuch, vol. I, p. 243.

[6] Bokai (Archiv. f. d. Path. u. Pharm., Bd. xxiv, 1888) shows that the fermentation of carbohydrate foods acts upon intestinal peristal-

In following out our plan of the dietetic treatment of constipation, then, having established our normal physiological diet for our individual, we include in it a fair proportion of the above special forms of food, varying the make-up according to the exact nature of our case and the circumstances of the patient.

Thus for the bread in the diet we advise black bread, or whole-wheat or rye bread, in place of white bread; for vegetables we give cabbage and beets, turnips, lettuce; for dessert we advise prunes or tamarinds.

If the feces show marked absence of fat we may try giving a large quantity of fat to promote a fat residue. If feces are already large in quantity, but action sluggish, we may be inclined to depend more upon the second class of foods, those containing organic acids and stimulant substances — the prunes and tamarinds — and to press these excessively.

Whatever the course we may adopt after study or experiment with our special case, we are providing a treatment for our condition entirely along physiological lines, providing natural methods of action and encouraging no mental or physical habits of artificial aids to action.

I have for the two last years been giving this system of treatment trial in all cases of simple habitual constipation which have come under my care. The general plan of treatment has been as follows:

Each case at the start, besides general directions as to hygiene and health, was instructed to give up the drugs which were in use for the constipation and to depend entirely upon the diet presented for this function.

A complete diet list, providing a diet of sufficient caloric value of mixed food elements, was written out, special emphasis being placed upon the foods of special value in constipation. As dessert, at one or two meals, depending upon the case, the patient was ordered a saucer of cooked prunes, about ten prunes at a time.

An example of the diet list which was written out for each patient at the start may be seen below. In the routine, simply the varieties of food were recorded, the quantity being to a certain extent left to the patient. With a list of this kind it is fairly safe to assume that a patient taking the usual quantities of the foods advised would get a sufficient total quantity to satisfy the normal standard of nutritive value.

The actual nutritive value of such a diet, given in prescribed quantities for each article of food, is given in the second part of the table appended.

Table 1.

DIET LIST FOR CONSTIPATION.

Plan diet in following manner, eating the usual quantity of foods presented and using the variety allowed in list:

Breakfast:
Cereal with cream and sugar — preferably corn meal, or rye and oats.
Two soft boiled or scrambled eggs.
Bread — preferably black bread, or pumpernickel, or rye bread, with much butter.
Fruit — apples or grapes.

Dinner:
Soup — preferably vegetable soup.
Fish or meat, or both, with salad.
Vegetables — at least two kinds, preferably spinach, cabbage, beets, turnips; potatoes, beans or peas if desired.
Dessert of rice or bread pudding or custard — including daily a saucer of prunes.

Supper:
Bread and butter.
Cocoa.
Cold meat and vegetable salad.
Dessert of stewed fruit — apples or pears or figs. If necessary include a saucer of prunes.
Drink at least three pints of water daily.

TABLE 2.

	Proteid, gm.	*Calories.*	*Mineral Salts, gm.*
Breakfast:			
200 gm. (about 6 oz.) porridge, oatmeal, rye, barley, Indian meal or wheat	4–6	150–200	4
8 gm. sugar or porridge		8	.001
1000 gm. milk or porridge	5–6	120–140	3
50 to 100 gm. bread, 1 to 3 slices	4–7	150–300	.5
15 gm. butter	.2	120	.5
2 eggs, or 50 gm. steak or chops	12	150–180	.5
Fruit: oranges, apples or grapes	0.5–1	50	.1
Dinner:			
120 gm. consommé or chicken broth, or potato, pea or tomato purée with salt	1–5	100–200	1
100 to 200 gm. beef, chicken, lamb, ham or sweetbread	20–25	200–400	1
Or 200 gm. bluefish, salmon, halibut, cod or mackerel	12–20	150–300	
50 gm. potatoes	1.5	60	.5
100 gm. spinach, asparagus or squash	1	100–200	.5
75 gm. peas, beans, macaroni or corn	9–15	300	3
Custard, or ice cream, or Indian pudding	6–15	150–250	1
Cheese and crackers	2–5	300	1
Supper:			
Bread and butter	5–7	200	1
Cocoa, one cup	6	150	1
Milk, one glass	8	200	3
Stewed fruit, pears, baked apples, peaches with cake, or griddle cakes	3–4	200–300	.1
	gm.	c.	gm.
Approximately,	80–130	2,650–3,600	21.71

Such a diet was maintained for one or two weeks. Enemata were used when necessary at the start. If at the end of the period the diet worked without aid from enemata, as was frequently the case, the patient was instructed to continue in it, gradually cutting down the prunes and possibly to some extent the proportion of fruits or green vegetables. In this way after a time an ordinary diet with plenty of green vegetables and fruit and an occasional prune dessert was approximated in many cases as a permanent habit.

In cases which were very much the victim of drug habit for their constipation, or in all cases which did not improve after ten days to two weeks

sis chiefly through its products of organic acids (lactic, butyric, acetic acids and the carbon dioxide). Schmidt (D. Archiv. f. klin. Med., Bd. vi, 1898) shows that the fermentation products of cellulose act upon the intestinal function.

of the above diet with the prunes, prunes stewed with a certain quantity of senna were prescribed (1 oz. of senna leaves placed in a cheese-cloth bag and stewed with three or four dozen prunes).

The patient was told to take a saucer of this dish for dessert once to thrice a day, according to need, in addition to his special diet. After one to three weeks the senna was omitted from the prunes (it was best to have this omitted without the knowledge of the patient if possible) and the patient continued on the regular constipation diet.

It was frequently necessary to use the senna at the start in cases which had depended much upon drugs. Given in the above way it was very easy to gradually lessen the dose while the general effect of the laxative diet was establishing itself, and the mental effect on the patient of the dosage given in this way was not at all the effect of giving a drug for laxative purposes.

In some special cases other methods, as the inclusion of fat excess in the diet, were tried. As a rule, however, the above plan was given and adhered to in all cases.

The treatment has now been tried upon 126 cases taken in routine with no selection of cases, excepting that cases with obvious pathological lesion as a probable cause of the condition, as tumor or definite disease of the alimentary tract, were sometimes excluded.

Of these 126 cases 100 were hospital cases and 26 private.

The plan was stated one year ago and all the cases included in the record have been under observation for six months or more. The result of the experiment up to date may be seen from the following table:

TABLE 3.

Total number of cases not heard from 68. (All hospital cases.)	
Total number of cases under observation 58.	
Number relieved by treatment 54.	
Of the 58 cases 40 were relieved by the diet alone, including prunes.	
The remaining 18 necessitated senna with the prunes at the start, but all save four of these have finally become able to continue on the diet alone without the senna.	

In most cases the relief came at once and continued. In a few it was a matter of one to several months before the result was accomplished, and frequently slight adaptation of the diet varying on the routine plan had to be made for the special individual, as the inclusion of excess of fat or of more organic acid in the diet.

These results indicate two facts very emphatically:

First, that in a very large majority of the cases of constipation which occur in the routine of practice, the chief if not the only cause or underlying condition is a failure of the individual to follow a normal physiological manner of life.

Second, that in a large majority of all cases of constipation taken without reference to the cause or underlying condition, a complete cure, so that the patient can get along without the regular use of drugs or other artificial aids, can be established by a proper direction of general régime and diet.

These results are the more encouraging since a large proportion of them were obtained in out-patient hospital patients, whose facility for carrying out the directions was limited. One cannot but feel that a treatment which could be so successful under these conditions is one thoroughly adapted to routine practice. On the whole, when we consider that all the patients treated already had the drug habit to some extent, the quick response to dietary régime is quite remarkable and was a great surprise to me, as also to the patients. It must be borne in mind, however, that these results were obtained under a method which included extreme attention to and study of the patient, much more than is accorded in the rule where a simple diet list is made out and the patient sent away to follow this indefinitely. This was, it is true, all that was done at the start, and the number of cures with this simple procedure alone was large. With many of the cases, however, very intimate study of the condition as to gastric digestion and motility investigated by study of the gastric contents, general metabolism as studied by quantitative analyses of the urine, intestinal digestion and absorption studied by examination of the feces and adaptation of the treatment to the findings in these regards, was necessary before success was forthcoming.

Taken all in all, however, the record is such as to confirm us in the surety that we have a method of treating constipation in a large majority of our cases which is effective and also ideal in that it follows the natural physiological method of accomplishing the function in question and does away with extraneous or drug stimulation.

HYPERCHLORHYDRIA.[1]

BY ROSCOE W. SWAN, M.D., WORCESTER, MASS.

A FAIRLY constant set of symptoms appear in about one-half of all stomach cases. They might be described in the following manner:

Usually persons from fifteen to forty years of age; in all walks of life, well-to-do and otherwise; no respect to position or social standing; but constant sufferers.

They will tell you that after eating a meal, say from one to three hours or more, they have a sensation of fullness in the epigastrium, with pains radiating through to the back and extending to the region of the heart, or extending over the abdomen. Oftentimes they have a burning sensation which is accompanied by eructations of a warm fluid rising in the mouth and called waterbrash, or is accompanied by expulsions of a foul-smelling gas, which has a choking sensation in the throat. If this gas does not make its appearance through the gullet, it remains long enough to produce marked distention of the stomach as well as acute colicky pain in the intestines.

After these conditions have lasted for months, and many different remedies have been tried

[1] Read before The Massachusetts Medical Society, June 9, 1903.

without results by as many different physicians, the patient becomes very irritable, despondent and even melancholy. Headaches appear, mostly hemicranial and periodic, leaving as abruptly as they begin, only to return shortly. The memory is poor, together with insomnia and depression. They round out a set of symptoms similar to neurasthenia, or marked anemia occurs. The appetite is almost always good and the weight is not changed. There is usually intense thirst, and the urine is free and frequent, is slightly acid in reaction, is deficient in chlorides and indican is increased. But at times the acid is diminished, and this diminution of acid in the urine during digestion is a rough measure of the increase of HCl in the gastric juice. Oftentimes there is nausea, with vomiting, preceded and followed by tenderness over the epigastrium.

At the time when the stomach is empty these patients are free from pain. The ingestion of food and drink almost immediately gives relief to the symptoms for a short time. These symptoms generally end with the evacuation of the stomach.

The bowels are usually sluggish.

All of these conditions correspond to a disease known and described as hyperchlorhydria, which has been spoken of so often of late that many different views are expressed about its supposed origin, and as many more about its course and treatment.

Many of these symptoms may arise directly from the stomach, or reflexly from the central nervous system, which in these cases suffers intensely at times through the absorption of toxins from the stomach.

Some authors deny the existence of persistent disorders of secretion which are not produced by an anatomical lesion of the gastric mucosa, and the majority of writers consider all the dynamic affections of secretion to be neuroses. No one will deny that secretion may be disturbed through the nerves which control it. Prolonged study and careful investigation have led to the conclusion that disorders of secretion are not always due to an alteration of the mucosa or to a neurosis of the vago-sympathetic system.

The normal stomach does not secrete when it is empty, and at most only 10 to 20 cc. of gastric contents can be removed when the tube is introduced into the normal stomach in the early morning before breakfast, but sometimes when the stomach tube is introduced at this time it will be found to contain more than 20 cc. of a liquid rich in HCl and the digestive ferments.

When a figure of acidity of 70 is reached after an Ewald's test breakfast, there is always present a hyperchlorhydria.

Hyperchlorhydria denotes a pathological increase of the HCl in the filtrate of the gastric contents at the acme of digestion.

The causes of hyperchlorhydria are those common to a large number of other diseases of the stomach and are as often found in the constitution and temperament as in the mode of life and the alimentation.

The abuses of condiments, the eating of large quantities of red meat, and imperfect mastication, are common causes. It is most frequent in the arthritic and the neuropath, in neurasthenia, hysteria and in melancholia. It is quite frequently associated with intestinal autointoxication. It is common in colilithiasis and renal lithiasis, in chlorosis and in nicotine poisoning and malaria.

Mental and moral causes play an important part. Cerebral fatigue may mark the beginning of the trouble and illustrates the close relations existing between the brain and the abdominal sympathetic.

The trouble may begin immediately after a particular meal, or it may be, and generally is, more gradually developed after a meal composed of starches, cereals, sweets, vegetables, fruits and fats, causing discomfort and pain at the height of gastric digestion.

The diagnosis of hyperchlorhydria can be frequently made by the existing subjective symptoms; discomfort or pain appearing one or two hours after meals, and alleviated by the ingestion of food or alkalies, speaks most prominently in favor of this condition. The diagnosis, however, is only a probable one, not yet positive. In order to make it decisive it is necessary to examine the gastric juice at the height of digestion. If too great acidity (caused by HCl) is found and the just-mentioned subjective symptoms prevail, the diagnosis of hyperchlorhydria is positive. The figure of acidity is one and one-half, sometimes double or three times as large as normal, the normal HCl being from $\frac{1}{10}$ to $\frac{2}{10}\%$.

The microscopic and chemical examination of the stomach contents after a test breakfast give us the most conclusive evidence as to existing conditions.

The examination of the blood is of great aid in drawing conclusions which will enable us to apply successful treatment to hyperchlorhydria. While all modes of research as to the pathological condition are important, the blood examinations are the most interesting if not the most important.

The differential diagnosis, in spite of the clear-cut features of the disease, may present some difficulties, and in some cases only a probable decision can be made.

Dyspepsia of liquids with supersecretion presents a very similar group of symptoms. The objective signs can alone differentiate the two diseases.

Displacements of the stomach may manifest the same subjective symptoms. The pain, however, is peristaltic, and due to the stomach trying to overcome the pyloric obstruction; is not removed by albuminous food, and milk may be badly borne. The physical and functional signs make the differentiation clear.

Hyperchlorhydria may be easily confounded with ulcer. HCl is not always in excess in gastric ulcer, although it may be a predisposing cause, and when doubt exists an ulcer cure should be prescribed. A hemorrhage large or small would exclude the functional trouble. Pain in

ulcer is not relieved by taking albuminous food. Otherwise the functional and subjective signs may be almost the same. The pain is increased by movements, and may be relieved by rest in a particular position.

Hyperasthenic gastritis resembles hyperchlorhydria even more closely than does ulcer. The gastritis is more directly traceable to diet and alcoholism.

The contents of the gastric juice after a test meal contains a large quantity of mucus and cell nuclei.

The signs differ only in degree and not in kind.

The prognosis is generally good; there are but few cases which resist all kinds of treatment, and for these in most instances complications (either some organic lesion of the stomach or of the central nervous syystem) must be looked for. In very old people an unfavorable prognosis must sometimes be given, as when the symptoms point to a malignant disease.

The diet for hyperchlorhydria is yet a subject of great controversy. Some clinicians forbid starchy foods entirely, and nourish their patients principally upon an animal diet. Their reason for forbidding the starches is that the amylolysis in hyperacidity is greatly diminished, the acid checking the conversion of starch into sugar quite early.

There is, on the other hand, quite a number of well-known clinicians who forbid meats to patients with hyperchlorhydria on account of their property to produce an increased flow of gastric juice. They prefer a milk diet and the carbohydrates.

On account of the variety of opinions advanced, one is justified in recommending the diet giving the best results, and in my own cases I prefer a mixed diet of a predominance of albumens and sparingly of the starchy food. Sweets increase the quantity but diminish the acidity of the gastric juice, and in moderate quantity are beneficial. Spices, condiments, acids, oils and alcoholic drinks should be absolutely prohibited.

The treatment consists in checking an excessive flow of gastric juice; and first among the remedies used is the extract of belladonna or its alkaloid, atropin. In the experiments carried out the amount of HCl was diminished from one-third to one-half the normal amount. The tendency which HCl has for combining with the different alkalies when brought in contact suggests the proper ones to use in hyperchlorhydria; that is, calcined magnesia combines with nearly twice its weight of HCl, and bicarbonate of soda combines with less than half its own weight.

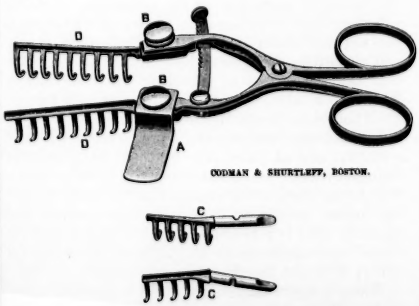
The best of results are obtained by combining magnesia and soda in such proportions as the urgency of the case requires, increasing or diminishing the magnesia as the bowels are confined or loose. Carlsbad salts reduce the amount of HCl, especially when prolonged over a period of four weeks at a fashionable health resort. Nitrate of silver in dose of 1-1000 by means of the intragastric spray gives fine results.

Lavage of the stomach will relieve the pain of a stubborn cramp in the region of the pylorus, there being nothing to do but to wash away the strong irritating acids. This is best followed by the intragastric spray of nitrate of silver.

It should not be overlooked, however, that there may be a chronic gastritis with a normal or an excess of acid. Here the alkalies are to be preferred to the salines, and should be administered warm.

Constipation will, as a rule, be relieved by the alkalies as soon as they neutralize the acidity. Then the carbohydrates to be digested pass through and stimulate the bowels to act. Rhubarb and soda, or large injections of, say, 8 oz. of olive oil, change of habitation from country to seashore, will overcome the cause. Massage of abdomen is followed by good results.

Hydrotherapy may be tried to suppress mental irritation. A cold sponge bath followed by brisk massage will accomplish much toward quieting the nerves.



As every organ is strengthened by activity and weakened by lack of exercise, one cannot urge too strongly the importance of diminishing the amount and number of artificial digestives employed in hyperchlorhydria.

New Instrument.

A MASTOID AND AURICLE RETRACTOR.[1]

BY FREDERICK L. JACK, M.D., BOSTON.

THE mastoid part of this instrument is a modification of Allport's retractor and Jansen's mouth gag. The additional simple device to hold the auricle is thought to be new. The following cut illustrates the many advantages of the instrument.

CODMAN & SHURTLEFF, BOSTON.

There are three sets of blades, varying in length to fit different lengths of incision. Two sets only are recommended. The teeth are placed close together and with the blades in position, the edges of the wound are widely separated so as not only to afford sufficient room for operating, but to control hemorrhage. The handles are

[1] Read before The American Otological Society, Washington, D.C., May 13, 1903.

pressed together like those of scissors and held in place by a ratchet. The instrument is quickly adjusted and absolutely self-retaining.

The auricle, which is often in the field of operation, requiring an assistant to hold it well forward out of the operative field, is now perfectly held aside by means of the ear tip. The tip (*A*) is simply a thin piece of metal adjusted to a groove in the head of screws. Both heads (*B*) are grooved so that it can be readily used for the right or left ear. After the retractor is in place, the upper half of the auricle is folded over and held in place by adjusting the tip in the groove.

Reports of Societies.

AMERICAN DERMATOLOGICAL ASSOCIATION.

TWENTY-SEVENTH ANNUAL MEETING, HELD AT WASHINGTON, D.C., MAY 12, 13, AND 14, 1903.

(Concluded from No. 11, page 298.)

SECOND DAY.

SOME OBSERVATIONS ON THE USE OF ROENTGEN RAYS IN DERMATOLOGY.

By DR. HENRY W. STELWAGON of Philadelphia. In this paper the author limited himself essentially to his own observations. He stated that in the x-rays we had a potent remedy in some cutaneous diseases, chiefly in some of the epitheliomata. It was also productive of benefit and even cure in some cases of lupus, scrofuloderma and other forms of cutaneous tuberculosis, and it would probably prove a permanent curative influence in some cases of lupus erythematosus. In other skin diseases, more especially acne of stubborn type and in acne rosacea, its effects were occasionally brilliant. In certain limited keratoses, especially of the palms and soles, it might be resorted to with a good chance of its being beneficial and occasionally curative. The same might be said also of the local forms of hyperidrosis. In eczema, psoriasis and other like comparatively inoffensive dermatoses he would reserve it for those cases which proved intractable to other plans of treatment. While recognizing the great value of this therapeutic agent in dermatology and that future observations might give it a still stronger hold, he has hesitated, as yet, from his own relatively limited experience, to subscribe without reservation to its possession of the almost marvelous powers accredited to it by other writers in so large a number of dermatoses.

THE RATIONALE OF AND THE INDICATIONS FOR THE THERAPEUTIC USE OF ROENTGEN RAYS.

By DR. WILLIAM A. PUSEY of Chicago. The author stated that the microscopical changes occurring in tissues affected by x-rays have been studied by various observers and their findings showed a striking uniformity. The first changes occurred in the epidermis. There was marked hyperplasia of the prickle-cell layer, with increase in the number of cells and increased formation of pigment and of keratohyalin, followed after further exposure by breaking up of nuclei or division of the nuclei; subsequently, there was degeneration of the cells and if the process proceeded further, complete disintegration. The changes in the corium were of a similarly striking character. The changes produced in diseased tissues were similar to those seen in normal tissues. The process was one primarily affecting the tissue cells; there was evidence first of stimulation of cellular activity and later, if the effect was intense, there followed derangement or disintegration of the affected cells. The changes occurred first and most strikingly in the epithelial structures and next in the blood vessels, but it was likely that they developed also, though to a much less degree, in the cells of all the tissues of the affected areas. From a consideration of the effect of x-rays upon tissues and upon bacteria in living tissues it was not difficult to arrive at a fairly accurate estimate of the indications for the therapeutic use of this agent. The actions of the x-rays which offered opportunities for therapeutic application were as follows:

(1) The action in causing atrophy of the appendages of the skin. (2) The destructive action upon organisms in living tissues. (3) The effect upon the metabolism of tissues. (4) The power of destroying certain pathological tissues. (5) The anodyne action, to which attention had been called by the effect upon pain in malignant growths, in neuralgias and in diseases of the skin accompanied by itching.

DR. L. A. DUHRING of Philadelphia said he was firmly impressed with the value of the Roentgen rays as a therapeutic agent in numerous diseases. He favored the use of the low vacuum tube.

DR. JAMES C. WHITE called attention to the possible injurious effects of the rays, even when the applications were made by men of great experience in the handling of the apparatus. The ultimate use of the rays should be confined to instances where the knife or cautery was not considered advisable.

DR. L. DUNCAN BULKLEY of New York emphasized the importance of measuring the dose of the remedy. He favored short exposures at close range and not too frequently repeated.

DR. F. H. WILLIAMS of Boston said that while the x-rays offered a remedy of much value in the treatment of skin diseases, it should be used with the greatest care. Some cases of even superficial new growths did not yield readily to the treatment and in some instances they were actually aggravated by it. Such cases, however, were uncommon. Another disadvantage was the long duration of the treatment.

DR. WILLIAM A. HARDAWAY of St. Louis said that while all were agreed as to the utility of the x-ray in malignant new growths of the skin, particularly in that type of growth approaching the rodent ulcer, there was some legitimate reason to doubt its value in acne and various other forms

of skin disease. He also spoke of the relapses that occasionally followed the treatment.

DR. E. B. BRONSON said the value of the x-rays was, in more ways than one, the burning question in therapeutics. In the application of the remedy there was still lacking a certain degree of precision. The essential feature was the amount of irradiation, and this depended, he thought, upon the condition of the tube. The actuating element he regarded of less importance.

DR. HARTZELL said that until physicists told us what the x-rays were and furnished us with apparatus to gauge the strength of the rays, we would be limited to the effects they produced. The time of the exposure must be determined by the effect produced. The same rule applied to other therapeutic agents. The proper dose in one case would be insufficient in another and too much in a third. He favored short exposures daily until a reaction occurred; then the intervals could be lengthened.

DR. FRANK HUGH MONTGOMERY of Chicago said that in the treatment of superficial epithelioma about the forehead, nose and cheeks with the x-rays, he had not seen one failure in at least over one hundred cases. In psoriasis the results were brilliant almost invariably, but the lesions recurred as fast as after other methods of treatment. In lichen planus the results were excellent. In acne he looked upon it as the ideal local treatment, but there were quite a number of cases in which, after the face had cleared, there was a return of the disease from outside.

DR. F. H. SHEPHERD said that x-ray burns were usually produced in the course of skiagraphic work and not in the treatment of skin diseases. He did not think the use of the x-rays should be advised in the treatment of epithelioma of the lower lip, on account of the usual involvement of the glands in the submaxillary region.

DR. MARTIN F. ENGMAN of St. Louis cited a case of epithelioma of the tongue successfully treated by the x-rays.

DR. A. P. BIDDLE of Detroit mentioned a case where the tube exploded, badly cutting the patient's cheek.

DR. JOHN T. BOWEN of Boston gave a brief review of the result of the Roentgen ray treatment in dermatology in the Massachusetts General Hospital during the past year. In all, 142 purely cutaneous diseases were treated by this method. This number was made up as follows: There were 55 cases of epithelioma, of which 27 were healed, 9 were benefited but failed to continue treatment and 19 were still under treatment. There were 4 cases of carcinoma; these were not benefited. Seventeen cases of keratosis senilis, 11 of which were cured, 4 were benefited but failed to continue treatment and 2 were still under treatment. There were 22 cases of tuberculosis, including lupus, verrucosa and scrofuloderma; 15 of these were healed, 4 were benefited but failed to continue treatment and 3 were still under treatment. There was 1 case of multiple round-cell sarcoma of the skin, which was not benefited. There were 12 cases of folliculitis, 8 of which were healed, 2 were benefited but failed to continue treatment and 2 were still under treatment. There were 7 cases of eczema, 5 of which were healed and 2 were still under treatment. There were 8 cases of psoriasis: 6 healed, 2 still under treatment. There were 4 cases of varicose ulcer, 2 healed: 1 benefited but failed to continue treatment, 1 still under treatment. There was 1 case of cellulitis of the leg, which failed to show any improvement. Two cases of varicose dermatitis: 1 healed; 1 benefited but failed to continue treatment. Two cases of acne; both healed. Two cases of hypertrichosis; both healed. Two cases of alopecia areata; not benefited. One case of erythema induratum; healed. One case of scleroderma; not improved. One case of hyperidrosis; not improved.

PROFESSIONAL DISCRETION: THE MEDICAL SECRET.

By DR. P. A. MORROW of New York. In this paper the author discussed the complicated problems that often confront the physician in dealing with patients suffering from venereal disease. On the one hand, he was bound by the obligations formulated in the precepts of the Hippocratic oath; on the other, by his duty to society at large. In the ordinary treatment of venereal disease he found it easy enough to adjust his line of conduct in strict accordance with his code of professional duty, as in such cases the individual interests of the patient alone were involved, but when a venereal patient consulted a physician in regard to marriage the situation was changed, then the interests of others might be jeopardized. His protective duty extended to the wife and future children and through them to society at large. There was no situation in the entire range of a professional man's experience so painful as to recognize himself powerless to prevent the morally culpable union of a syphilitic man and an innocent woman. What had been termed the "eternal problem" of the professional secret had long engaged the thoughtful attention of medical men. Like all problems connected with the prophylaxis of venereal disease, it was exceedingly complex and baffling. It might be said that no solution of these problems had ever been proposed, no plan of action for the regulation or control of these diseases had ever been formulated, which did not come in conflict with individual liberty, legal rights or moral principles. In the larger proportion of cases, venereal diseases were introduced into marriage from extra-conjugal infections, contracted *post nuptias*. Here it was evident that the preventive duty of the physician could not be exercised. Other phases of the subject discussed by Dr. Morrow in his paper were the relation of the physician to the syphilitic husband or wife, to the syphilitic nurse, syphilis in domestic servants and lastly, industrial infections.

DR. GILCRIST said he thought syphilis should be regarded from the same standpoint as smallpox. It should be looked upon as a highly contagious disease.

DR. STELWAGON called attention to the fact that many hospitals refused to accept venereal

patients, on the ground that it would encourage vice. Physicians themselves, he thought, were partly to blame for the increase in venereal diseases, as they were too apt to belittle this class of affections.

Dr. H. G. Klotz of New York advised the wide dissemination of a knowledge of the dangers attending the contraction of venereal diseases. The subject should be handled without gloves. Syphilis was not a venereal disease, but a disease of the public.

NOTE ON A METHOD OF EARLY DIAGNOSIS IN A CASE OF LEPROSY.

By Dr. Francis J. Shepherd of Montreal. The patient, a Chinaman, was admitted to the Montreal General Hospital with a skin affection of an erythematous type. Leprosy was suspected and the city authorities were anxious for a positive diagnosis in order that the patient, if suffering from leprosy, might be sent home. The ulnar nerves were enlarged. A section was removed from one of them and on examination it was found to contain numbers of the bacilli of leprosy. Thus the diagnosis was positively established.

Dr. Frank H. Montgomery of Chicago called attention to the early involvement of the posterior auricular nerve in leprosy. According to one authority, it was involved in 90% of all cases of anesthetic leprosy and much earlier than the ulnar nerve.

Dr. Morrow said that in a very large proportion of cases of leprosy the identification of the lepra bacillus was easily made in the nasal secretions.

DERMATITIS VENENATA — A SUPPLEMENTAL LIST.

By Dr. James C. White of Boston. In this paper the author placed on record for convenient reference a list of the agents which had been observed to produce inflammation of the skin by contact since the publication of his work on Dermatitis Venenata in 1887. Some of these had already been described by him from time to time. The list included chlorhydrat-paraphenyl-diamin; (found in certain hair dyes), aureole, also used as a hair dye; orthoform; salol; resorcin; aristol; ichthol; dermatol; europhen; pyoctanin; creolin; iodvasogen; kerosene; electricity; aurantia, an orange-colored dye used to stain leather; cocus wood; guiacum; humulus; heracleum; angelica; hyacinth; Ginkgo tree; cotoneaster; humea.

Dr. Morrow called attention to the importance of a very thorough investigation in every case of dermatitis venenata. Many innocent plants have obtained a bad reputation for toxic effects simply from misinterpretation.

Mr. V. K. Chesnut of the United States Department of Agriculture said the most common causes of skin poisoning from plants were the poison-ivy and the sumac, both of which were very widely distributed in this country. He stated that persons who handled radishes in abundance were apt to be poisoned.

Dr. Stelwagon said that the drug metol, used by photographers in the development of negatives, often produced a varying degree of dermatitis of the hands and sometimes of the face.

Dr. Gilcrist mentioned a case where an eczematous eruption was produced by a weak solution of boracic acid, used as a rectal injection. Dr. Klotz said he had observed the same thing in cases where the drug was used for irrigating the bladder in cystitis.

Dr. James C. White in closing said that while it was a popular belief that ivy poisoning might recur spontaneously a year after the original attack, he did not regard that theory as at all plausible; there were no grounds for it. On the other hand the skin of a person who had once been poisoned by ivy was no doubt more susceptible and with the onset of warm weather, eczematous lesions or other forms of dermatitis might occur. It was well known that the poison of the ivy vine was quite evanescent.

A NEW DRUG ERUPTION OF THE IODOFORM TYPE.

Dr. S. Pollitzer of New York read this paper. He reported a number of cases of dermatitis, of a vesicular and crusted type, resulting from the external use of mesotan, which was described chemically as a methyl-oxymethyl-ester of salicylic acid. Mesotan was a comparatively new remedy for rheumatism and was applied externally over the affected parts, after diluting it with an equal volume of olive oil. The local application of the remedy was promptly followed by an agreeable sensation of warmth and tingling, the skin became reddened and within half an hour after its application, salicylic acid could be detected in the urine.

REPORT OF A CASE OF DERMATITIS GANGRENOSA INFANTUM.

By Drs. J. Nevins Hyde and E. R. LeCount of Chicago. The patient, an infant seventeen months old, had always been in good health, with the exception of a single attack of bowel disorder, from which it had promptly recovered. It had walked at the twelfth month and had accomplished the normal eruption of teeth. There was no history of varicella, variola or vaccination. The family history was good and there was no record of unhygienic surroundings in the home. The child was admitted to the hospital on Feb. 15, 1903. Ten days before, the mother had first noticed some reddish blotches on the abdominal surface of the child. Two days later, beginning with the left hand, the fingers became yellowish-red in color and much swollen. Gradually, the involved digits assumed a darker hue. A physician was summoned on the third day, who incised the tumefaction between the fingers, with the result of liberating a "watery fluid." On the fifth day of the disease, eruptive lesions appeared on the back, the feet became swollen and much discolored. At the time of admission, the child's temperature was 104° F.; there was considerable stupor and the child moaned occasionally. The abdominal surface was symmetrically and rather

thickly overspread with superficial, globular, discrete pustules, as large as split peas, well defined and distended and having a grayish-white color. They were neither umbilicated nor superimposed upon papules of similar size. On the extremities they were less numerous and conspicuous. The back was equally involved with the abdominal surface, but the lesions were obviously more abundant in the regions of pressure. On the eleventh day a marked change occurred in the eruptive phenomena, superficial papulo-pustules cropping out among pustulo-bullous lesions and there were decidedly more numerous and more deeply encroaching gangrenous areas where the lesions were large and threatening. The parts about the radial border of the left hand were in a gangrenous state. The left foot was swollen, cold and blackened; the right foot was similarly involved, though less extensively. Several of the digits of both the hands and feet were attached to the limb merely by tags of gangrenous tissue and eventually one of them became practically separated from the limb by the morbid process. Death occurred on the fifteenth day of the disease.

REPORT OF A CASE OF SYMMETRICAL GANGRENE.

DR. E. B. BRONSON of New York reported a case of symmetrical gangrene affecting the lower extremities. The patient was a girl who had always apparently enjoyed good health. She was thirteen years old when the affection was first noticed. The family history was fairly good, although it showed some gouty and neurotic tendencies. The patient had had no severe illness and though of a nervous temperament, she possessed good self-control and normal mentality and had never given the slightest indications of hysteria. The disease began some eight years ago and from beginning to end had occupied the same regions. The lesions were exactly symmetrical. There were areas over the shins, at the junction of the middle and lower third of the legs and on each side of both ankles behind the malleoli. The first attack came on in summer and for several years the succeeding attacks occurred in that season. About five years ago they began to occur in the winter also. Their most important feature was pain, which was both burning and lancinating in character and at times intense. This was accompanied with a dusky redness, heat and swelling and occasionally excoriations; the latter the patient thought were usually the result of the severe treatment to which she was subjected, namely, caustics and at times curetting. There was never any ischemia nor coldness of the affected parts. The attacks lasted usually about six weeks and there were seldom more than two or three attacks in the course of a year. At one time, some two years ago, there was an intermission of eighteen months between the attacks. Commencing last May or June, there was a continuous attack lasting until the middle of October; it was the severest of all and attended by the development of deep gangrene — usually on the shins. After the gangrene had reached its fullest extent, the pain rather suddenly ceased, but the dry, black sloughs showed very little tendency to separate and after waiting a month or more they were removed by the knife, it being necessary to cut almost to the bone before reaching healthy, living tissue. Since then (six months ago) there had been no recurrence of the disease.

THIRD DAY.

A CASE OF MULTIPLE ANGIOMA.

DR. ABNER POST of Boston reported this case. The patient was an under-sized but apparently healthy girl of sixteen who bore upon her right arm a series of curious outgrowths or tumors which practically occupied the whole of the palm and extended in scattered nodules to the sternum. The first growth appeared on the arm when the patient was one year old. The arm gradually became swollen, of a bluish color and an irregular, lumpy outline. Shortly afterwards a puffiness of the hand was noticed, which also underwent the same change. During the past six or seven years similar spots had developed on the chest. Six years ago, a number of the superficial elevations were cut away, but they recurred in practically the same locations. A microscopical examination of the tumors proved them to be hemangiomata.

THE PRESENT STATUS OF PHOTOTHERAPY.

By DR. FRANK HUGH MONTGOMERY of Chicago. The paper was based on the author's recent observations in the Copenhagen and other light institutes, on published reports and on the personal experience of Dr. James Nevins Hyde and his own. He stated that in lupus vulgaris no other treatment was so uniformly successful or gave such good results from a cosmetic standpoint. The x-rays had given equally good results in some cases, but were more dangerous and the resulting scars were not always so good. Phototherapy was also of great value in the treatment of lupus erythematosus. It had given good results also in some cases of rosacea, vascular nevi, alopecia areata, indolent ulcers, acne and superficial epithelioma. In the two last-named diseases, the x-rays were, however, equally efficacious, more convenient and less expensive. In Finsen's Institute (Copenhagen), as the result of improvements in the apparatus, the time (and therefore the expense) of the treatment had been reduced to one-fourth that required in cases treated prior to 1901. A new and inexpensive lamp for the treatment of a single patient had been devised by Professor Finsen and Dr. Reyn. It was built on the same principles as the larger apparatus and was equally effective. Of the many other small lamps on the market, some were of value in the treatment of superficial lesions, but, as shown by clinical and laboratory tests, none had the penetrating power of the concentrated Finsen light and all were therefore ineffective in deeper-seated disease. The most refrangible ultra-violet rays, which were highly bactericidal for surface cultures, penetrated the epidermis less than

one millimeter. The effective light was found in the visible blue and violet, with possibly a few of the immediately adjacent ultra-violet rays. Finsen believed that the reported failures of the red-light treatment of smallpox were due to imperfect technique. He hung in the room with the patient a number of sensitized photographer's plates. If, at the end of the treatment, these plates showed the influence of white light, the technique had been defective.

Dr. George Thomas Jackson of New York showed one of the small lamps devised by Dr. Piffard, which was very rich in ultra-violet rays. The London lamp had been used at the Presbyterian Hospital during the past year, with varying success. In one case of epithelioma of perhaps six months' standing, the lesion, which was a superficial one, disappeared after three exposures to the light. Regarding the length of the exposure, Dr. Jackson said he had no fast rule. Sometimes an exposure of five minutes gave rise to an intense dermatitis, while in another case there might be no reaction after an exposure of twenty-five minutes.

Dr. William A. Pusey of Chicago said he had been interested in comparing the effects of phototherapy and radiotherapy, and it seemed to him that there were one or two conditions in which the former was preferable. There was a field of usefulness for phototherapy in the treatment of flat nevi and in conditions where it was desirable to produce an inflammatory reaction and be on the safe side. It was safer than radiotherapy.

Dr. E. B. Bronson said the effective agent in phototherapy was not the ultra-violet rays alone or even chiefly. Finsen had demonstrated very effectively, by experiments on rabbits, that there was a wide disparity between the penetrability of the different lamps. The penetrability depended not on the ultra-violet rays alone, but on the visible rays as well.

Dr. Montgomery, in closing, said there was no question that light rays were highly bactericidal on the surface,—the vast majority of bacteria were destroyed very rapidly by the ultra-violet rays.

SOME PRE-CANCEROUS AFFECTIONS OF THE SKIN, MORE PARTICULARLY PRE-CANCEROUS KERATOSES.

Dr. M. B. Hartzell of Philadelphia read this paper. He stated that a small number of diseases of the skin, after existing for a longer or shorter period as benign affections, exhibiting neither the clinical nor the histological features of malignancy, might terminate in epithelioma. This termination, although far from being the rule, occurred in a sufficient number of cases to exclude the probability of mere coincidence and to warrant the application of the term pre-cancerous to such affections. These diseases did not belong to a single pathological group, but included inflammations, neoplasms, hypertrophies and such alterations of the skin as might result from previous disease or injury. In this list of pre-cancerous affections, Dr. Hartzell included the following: Paraffin dermatitis, a peculiar inflammation of the skin occurring in workers in tar and paraffin; the dermatitis of the scrotum met with in chimney sweeps, due to the irritation of soot; lupus vulgaris, in a small proportion of cases; other forms of cutaneous tuberculosis, such as tuberculosis cutis verrucosa; rarely, after lupus erythematosus; new growths of the skin, congenital or acquired; pigmented nevi; chronic leg ulcers; cicatrices arising from any cause, but more particularly those resulting from burns; various forms of circumscribed keratoses, such as cutaneous horns and callosities; arsenical keratoses; the so-called senile seborrhea, a better name for which was the senile keratoma of Besnier. The latter Dr. Hartzell regarded as the most frequent and perhaps the most important form of pre-cancerous keratosis.

Dr. James C. White of Boston mentioned a case of epithelioma of the hand following a prolonged x-ray dermatitis.

Dr. Pusey said he had recently had the opportunity of studying a remarkable case of chronic x-ray dermatitis in a man who manufactured apparatus for producing the rays. He was burned from the middle of the trunk upwards, the lesions resembling those of xeroderma pigmentosa. Subsequently he developed an epithelioma, for which his hand had to be amputated.

Dr. Stelwagon said he had seen a number of examples of chronic x-ray poisoning in which there were decided keratoses that pointed suspiciously towards the development of epithelioma.

Dr. Martin F. Engman of St. Louis said he thought that sunlight might possibly have something to do with the development of senile keratoses. The lesions occurred most frequently on exposed parts.

Dr. L. A. Duhring reported a case of typical lupus erythematosus followed by the development of carcinoma. He had never seen a similar case.

Dr. S. Pollitzer of New York thought that epithelioma following lupus, whether of the vulgaris or erythematosus type, might depend upon the mechanical methods of treatment employed. Otherwise it was difficult to see why an inflammatory process like lupus should result in epithelioma more frequently than any other inflammatory disease.

PALUDIDES, WITH THE HISTOPATHOLOGY OF A CASE OF MALARIAL PURPURA.

By Dr. Martin F. Engman of St. Louis. In using the word "paludide," the author followed the suggestion of Vernuiel and Merklen and also Brocq to express the probable origin of certain familar eruptions associated with malarial infection. In the cases he reported, twenty-four in all, the malarial plasmodium was demonstrated in the blood. The list included herpes simplex, herpes zoster, pompholyx, urticaria, angioneurotic edema, trophic changes in the skin (non-inflammatory pityriasis), erythema multiforme, purpura and gangrene. He did not attempt to express an opinion as to why so many different types of erup-

tion should emanate from the same source, nor did he wish to be understood as claiming that these eruptions were peculiarly malarial in origin; therefore, the term "paludide" was not used in the sense that one employed the word "tuberculide" or "syphilide." The object of the paper was to point out the necessity of blood examinations in eruptions with any semblance of periodicity of their symptoms. Many of the paludal dermatoses were not accompanied by any constitutional symptoms, pyrexia, chills, etc., the dermal symptoms being the only manifestations of the infection. In the histologic examination of a paludal purpura the lymph channels were widely dilated, the superficial vessels were empty and the deeper ones engorged. There were marked symptoms of edema and slight diapedesis of red cells from the deeper vessels. No thrombi were found.

The PRESIDENT, DR. BOWEN, said he did not think the term "paludides" was an especially fitting one. While malaria was the cause of the eruptions in the cases reported by Dr. Engman, similar eruptions were also produced by other causes.

The following officers were elected for the ensuing year: President, DR. JOSEPH ZEISLER of Chicago; Vice-President, DR. M. B. HARTZELL of Philadelphia; Secretary and Treasurer, DR. CHARLES J. WHITE of Boston. Niagara Falls was selected as the place of next meeting, which will be held early in June, 1904.

Recent Literature.

Physiological Aspects of the Liquor Problem. Investigations made by and under the direction of W. O. ATWATER, JOHN S. BILLINGS, H. P. BOWDITCH, R. H. CHITTENDEN and W. H. WELCH, Sub-Committee of the Committee of Fifty to investigate the liquor problem. Vol. I, pp. xxii, 396. Vol. II, pp. 379. Boston and New York: Houghton, Mifflin & Co. 1903.

As indicated on the title pages, these books represent the work and preliminary conclusions of a systematic investigation of the alcohol problem in all its bearings, undertaken under the auspices of the so-called Committee of Fifty. The immediate research was carried out by a sub-committee, composed of men of science, and others particularly versed in the various aspects of the alcohol question in its social, physiological and pharmacological bearings. The general result is a work of very great significance, containing as it does the most reliable experimental data yet collected on the subject, and a vast number of facts regarded from various points of view bearing on the general question.

At the beginning of the first volume, the authors have very wisely given, in small compass, their report, which includes methods of investigation as well as results. Some of the general conclusions reached may be summarized as follows: Experimental evidence is of doubtful value in determining individual susceptibility to alcohol in man; from somewhat untrustworthy data it is probable that of adult males in this country, not more than 20% are total abstainers and not more than 5% are positively intemperate; 80% of brain workers use alcoholic drinks to some extent; the injurious effect of an alcoholic drink is due mainly to the alcohol it contains; cheap liquors are not so injurious as ordinarily supposed; the question as to whether alcohol is a food or a poison depends upon idiosyncrasy and amount; alcoholic drinks may be temporary restoratives, but they probably lessen the power of the organism to resist infectious or contagious disease; so-called scientific temperance instruction in public schools is unscientific and undesirable; children should be taught certain definite facts regarding alcohol, but should be guarded against false impressions.

The book is mainly taken up with detailed papers on various aspects of the alcohol problem, considered largely from the laboratory side, of which the foregoing summary gives the main results. The report by Dr. H. P. Bowditch and Dr. C. F. Hodge on the "Present Instruction on the Physiological Action of Alcohol" will no doubt be read with very particular interest. It is an exhaustive and fair criticism and arraignment of the so-called scientific temperance instruction, with which the name of Mrs. Mary H. Hunt is chiefly identified.

Educators and legislators alike should read and ponder this section. It cannot fail to have influence in modifying the present most unfortunate state of affairs. To a careful student of the subject the articles by Chittenden, Billings, Abel, Atwater and Welch will also be read with much profit. We regret that a clinician's point of view is not appended.

The general feeling one has on putting the book down is of gratification that so systematic a treatise has been published on a subject of such vital general importance, and also that much remains to be done before the involved questions may be said to have received a definite scientific answer. In the meantime we are convinced that the publication of this book will serve as a means of enlightenment to the great mass of intelligent but uninformed persons, whose concern it is to take a sane attitude in a question of this import.

An English Handbook to the Paris Medical School. By A. A. WARDEN, M.D., with prefatory letters by LORD LISTER and Prof. W. W. KEEN. London: J. and A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1903.

The difficulties of finding one's medical way about Paris are met by this small book. It is well arranged, and gives the information a student needs in planning a course of study in that city. It is replete with facts of importance.

THE BOSTON

Medical and Surgical Journal

THURSDAY, SEPTEMBER 17, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

THE ALLEVIATION OF TUBERCULOSIS.

One of the hopeful signs in the conflict with tuberculosis is the increasing tendency to spread knowledge by popular means which shall not unduly alarm the community but which shall have the tendency to spread the knowledge which should and must be known if the dangers of infection are to be avoided. So radical a change has come upon us in our estimate of the character of tuberculosis that the following statement from the pen of Dr. Lawrence F. Flick, founder of the Pennsylvania Society for the Prevention of Tuberculosis, is possible:

> Some men, in their zeal to save human life, recently have ridden the false theory of heredity of consumption so far as to want to forbid by law marriage to all consumptives. The enactment of such a law would be utterly unwarranted.
>
> Consumption is not inherited. On the contrary, immunity gradually comes to those in whose ancestry the disease has existed.
>
> What immunity the white race enjoys has come to it through heredity. It is to children of consumptive parents that we owe the protection we now possess.
>
> Life, therefore, would not be saved by prohibition of marriage between consumptives. On the contrary, the conserving power of nature would be handicapped in its operation.

How true this may be it is not our purpose to discuss, but the fact remains that heredity, with all the untold misery which that word signifies in the popular mind, has begun at least to be eradicated from consideration in the treatment of tuberculous persons. This is certainly valuable in so far as it lays stress upon what all must consider the essential element in prevention, that is, the care of the individual tuberculous person.

We have before us a circular issued by an association in a neighboring town, the function of which is to cure at home, if possible, persons suffering from tuberculosis, to relieve with food all needy tuberculous persons, to educate the entire community in the cure and prevention of the disease, and to promote the establishment of hospitals for hopeless cases. This association, although apparently organized by laymen, has the interest and co-operation of prominent physicians. This sort of propaganda, under persons of proper knowledge and ability to meet the difficult questions which are sure to arise, is wholly to be commended; in fact, it is only through the education of the public that the eradication of tuberculosis is to be expected, and this naturally may be best brought about by a general campaign inaugurated by the people themselves. This movement, of which we have just spoken, is intended to be largely educational, and among other means to this end there will be on file at designated places, and open to the public, reports from other organizations working along similar lines, reprints of medical papers relating to the general subject and pamphlets descriptive of sanatoria. We wish this society, and all others with a similar purpose in view, the greatest possible measure of success.

AN EPIDEMIC OF TYPHOID FEVER UNDER PECULIAR CIRCUMSTANCES.

Nothing has been more conclusively demonstrated in the experience of the Merrimac River cities, as well as in other communities, than the danger of using as drinking water a supply taken from a polluted stream without purification. Measures of different character have been taken by these industrial cities for improving their water supplies, whereby the deathrate from typhoid fever has been very greatly diminished in them. In the two larger manufacturing cities of Lowell and Lawrence, systems of canals are in use for supplying the needed water for the mills, and in the mills this water is generally used for washing purposes and for the supply of closets, etc., although it is much more polluted than that of the river and consequently entirely unfit for drinking.

On the night of July 18 a serious fire occurred in Lowell at one of the mills, where, for a few hours only, it became necessary to increase the supply needed for fire purposes. By some defect the polluted water of the canals for a short time probably gained access to the pipes used for the distribution of the public supply. Within a few

days from the date of the fire, there was a marked increase in the amount of diarrheal diseases generally throughout the city and on July 31 cases of typhoid fever began to be reported until the whole number reported up to Aug. 31 was 153.[1] The number of cases of typhoid fever reported in July were only five, being one each on the 1st, 8th, 23d, 25th and 31st.

The cases reported in August were as follows:

Dates,	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
Cases,	6	2	3	6	4	6	6	9	8	7	5	15	8	8	9	3	7	8	7	9	5
Dates,	22	23	24	25	26	27	28														
Cases,	0	1	0	4	1	2	2														

Total in August, 151.

The occurrence of this epidemic emphasizes the fact that measures intended for the protection of life and health are of higher importance than those which are taken for the protection of property alone, and those which are intended or used for the latter only should not be so arranged as to imperil the former.

DEPARTMENT STORE PHARMACY.

A SAMPLE of beeswax was recently obtained at a department store in Boston, which, in order to please the multitude of its patrons, maintains a drug counter. The sample was sent to the State Board of Health for analysis (since the board is authorized to carry on an inspection of food and drugs), and was found to be largely adulterated. Whereupon the board sent a notice to the proprietor of the department store informing him of the fact that his *cera flava* was adulterated.

The following reply was received by the Board:

BOSTON, July —, 1903.

Gentlemen:—We are in receipt of enclosed (notice), dated July —, and are unable to learn what you refer to. We are informed that "*Cera flava*" is the Latin for prepared meal. We have so many kinds that we cannot (if this is what you refer to) discover which one. If you will kindly make it plain to us, we will make further investigation.

Respectfully yours,

"We are also informed" that the principal items of sale at these department store drug counters are cosmetics, tonics, bitters, "blood purifiers" and other proprietary articles, while the legitimate and officinal articles of the pharmacopeia are but little sought for, hence possibly the lack of familiarity with the latter on the part of the proprietor. This being the case, it would not be at all surprising if accidents should occur in such establishments, not merely on account of carelessness, but on account of sheer ignorance of pharmaceutical work.

[1] This number 153 includes the two cases reported on July 25 and 31. The dates given above are those on which the patients were taken sick, not the actual date of reporting, the latter being occasionally unreliable.

SEX IN INDUSTRY.

THE Massachusetts Bureau of Labor Statistics has issued a reprint in advance of its Thirty-third Annual Report, in which are presented the numbers of persons of each sex employed in gainful occupations in the State in the census year 1895. The number of persons thus employed in 1895 was 1,079,090, of whom 27.1% were women as compared with 26.8% in 1890, 24.2% in 1880 and 22.1% in 1870.

In the principal groups of employed persons, females were found as follows:

In government occupations, national, state and municipal, 14.2%; professional occupations, 45.5%; domestic service, 84.3%; personal service, 43.4%; trade, 15.7%; transportation, 0.5%; agriculture, 0.7%; fisheries, 0.2%; manufactures, 29.0%; mining, 0.0%; laborers, 0.2%; apprentices, 9.6%; children at work, 41.8%. As a matter of interest it appears that one woman followed the occupation of blacksmith out of 6,604 thus employed, three were carpenters out of 28,578, nine were engineers, five firemen (or women), one teamster, one cobbler, one scissors grinder.

Out of all the female workers in the State 88% are unmarried. Over 100,000 are in factories, 79,000 are servants and 20,000 practice professions. An increasing number of women appear to prefer freedom, work and an income to married life.

Turning to the figures which are specially interesting to medical men, the results of enumeration as presented are unsatisfactory, unscientific and misleading. Under the general head of medicine are embraced 5,800 persons, 5,114 of whom are men and 686 women, but in this general class or group are included clairvoyants, chiropodists, dentists, manicures, midwives, veterinary surgeons, physicians, and physicians and surgeons.

The number of physicians and physicians and surgeons who were willing to answer to the nickname of "allopaths" was 1,432, of whom 56 were females. There were also 385 who answered to the name of "homeopaths," 83 eclectics, 77 specialists and 2,213 who were not specified. Of the 4,188 persons employed in the profession of medicine, 486 were females.

The useless character of this classification is apparent upon consulting the latest catalogues of the members of the two largest medical organizations of the State, the Massachusetts Medical Society and the Massachusetts Homeopathic Medical Society, the former of which shows a list of 2,607 members and the latter 328 members. Under the head of "personal service" 4,810 persons are grouped as nurses, of whom 4,473 were women. On pp. 247–250 are reproduced several tables, said to be "drawn from official sources," that is, the State Registration reports, in which the original blunders of those reports are copied *in ipsissimis verbis*, but with the addition of others not in the original reports, the term "marriage rate" in each instance being confounded with the rate of persons married per 1,000 population.

MEDICAL NOTES.

THE CAUSE OF POPE LEO'S DEATH. — Profitless as such discussion now is, a difference of opinion has arisen among Italian physicians regarding the cause of Pope Leo's death Professor Cardarelli has published a statement for the purpose of demonstrating that death was due either to cancer of the pleura or tuberculous hydrothorax. This is not in accord with the opinion and postmortem examination given out by Drs. Lapponi and Mazzoni, who regarded the final illness as pleurisy or pleuro-pneumonia. It is probable that the matter will not now be decided to the satisfaction of either of the disputants.

ENLARGEMENT OF PORTSMOUTH, VA., NAVAL HOSPITAL. — It is said that Surgeon-General Rixey will advocate an enlargement of the General Naval Hospital at Portsmouth, Va. At present the accommodations are for two hundred patients, and it is proposed to enlarge the hospital so that it will accommodate five hundred. Isolation wards will also be provided.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Sept. 16, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 28, scarlatina 17, typhoid fever 27, measles 11, smallpox 0.

BOSTON FLOATING HOSPITAL. — The last trip of the Boston Floating Hospital for the year was made Sept. 14. The managers would have been glad to have continued further into September had the necessary funds been forthcoming. The summer has been, in many respects, more satisfactory, as regards work accomplished, than any preceding season, though much more could have been done with a more commodious boat.

NEW YORK.

OPENING OF MEDICAL DEPARTMENT, COLUMBIA UNIVERSITY. — It is announced that the opening exercises of the Columbia University College of Physicians and Surgeons for the academic year 1903–04 will be held Thursday, Sept. 24, 1903, at three o'clock. After a brief address of welcome by the president of the university an address will be delivered by Walter B. James, M.D., Professor of the Practice of Medicine, upon "The Old and the New Medicine." Seats will be reserved for the Trustees of the University, for members of the Faculty and for other officers of instruction.

NEW YORK'S WATER SUPPLY. — The announcement has been made that the forthcoming report of the commission of three experts, headed by Prof. William H. Burr of Columbia University, appointed by the mayor to examine into the available sources for an increased water supply for the city, will contain six propositions regarding the subject. Three will deal with the Croton watershed, one with a modified plan of the Ramapo project, which some time ago obtained notoriety as a threatened political job, a fifth with the storage possibilities of the Adirondack region and the sixth with a Catskill Mountain storage proposition that is entirely new. This last contemplates the construction of an enormous reservoir on Esopus Creek, west of the Hudson River in Ulster County. For some time engineers have been at work along the course of this stream, and one of the best reservoir sites has been shown to be at Bishop Falls, near Spokane in the western Catskills, on the line of the Ulster and Delaware Railroad. Surveys and measurements have already been made here and specifications have been outlined, so that the proximate expense of such a reservoir can be pointed out in the report. By damming up a section at this location it has been found that an area of eight square miles could be utilized as a natural reservoir, and that a very large supply of water could be obtained at comparatively small expense. The scheme suggested contemplates carrying the water in an aqueduct under the Hudson River near Kingston, and thence down the east side of the river. It is estimated

that the construction of the whole work would take ten years, at the end of which time New York would have one of the most satisfactory water plants in the world, and at a cost that would be at a minimum per gallon furnished.

MEDICAL INSPECTION OF SCHOOL CHILDREN. — Just previous to the opening of the public schools for the season on Sept. 14, the president of the Board of Health made assignment of fifty-five medical inspectors and thirty trained nurses to the stations at which examinations were to be made of all children entering the schools. The corps of physicians and nurses work under the direction of Dr. J. J. Cronin of the Health Department. All pupils found to be affected with trachoma, ringworm, whooping-cough or other contagious disease are required to be conducted by the nurses to their homes, where their parents or guardians are advised in reference to securing medical attendance for the children and as to such hygienic care as will contribute to their return to school at as early a period as possible. The inspections will, of course, be continued throughout the school year.

RECREATION CENTERS. — The Department of Education has designated seventeen school buildings in the borough of Manhattan and three in Brooklyn as recreation centers during the coming season, and an invitation to the use of these is extended to all working boys and girls. At each of the schools provision is made for systematic training in gymnastics and athletic sports, as well as for reading and quiet games and the encouragement of literary and debating clubs. In addition, a study room is provided where students can obtain special preparation for civil service and regents' examinations, and the various departments are to be open every night in the week except Sunday.

A "CHRISTIAN SCIENCE" DIFFICULTY. — Dr. L. J. McAdam of Buffalo was recently called to see a child in a Christian Science family at death's door from a "mortal thought" of diphtheria. He was not allowed to prescribe, however; the parents, who no doubt feared legal inconveniences for themselves, stating that all they wanted from him was a death certificate. Dr. McAdam very properly refused to give this, and immediately reported the case to the proper authorities.

SMALL DAMAGES TO A PHYSICIAN. — Dr. Hubbard N. Mitchell of New York has received an award of only $700 in a suit brought by him in the Supreme Court at Jersey City against the Jersey City, Hoboken and Paterson Street Railway Company, in which he claimed $50,000 damages. In an accident last year, in which a car of this company in which he was riding was derailed, Dr. Mitchell was thrown down, his head striking the seat on the opposite side. In consequence of the injury received he claimed that he became deaf in his left ear, which was specially trained for auscultatory purposes, and that as a result, his practice, which he stated to have been previously worth $30,000 a year, had been interferred with to a most serious extent.

NOTES FROM THE PHILIPPINES.

LIBRARY OF GOVERNMENT LABORATORIES. — The library of the government laboratories in Manila has recently been increased by the addition of about a thousand new books of reference, chiefly in German and French. This library is already the best and most complete scientific library in the Orient, the books all being of the latest editions and chosen with especial care, and files of all the leading medical journals of the world being maintained. While this library is primarily for the use of officials of the government, its use by the physicians of Manila is invited, and its sphere of usefulness thereby much enlarged.

WORK IN GOVERNMENT LABORATORY. — Work on the new government laboratory is progressing slowly as a result of the difficulty in obtaining suitable labor and proper material. It is semi-officially announced that the building will be ready for occupancy on Jan. 1, 1904, but the work can scarcely be completed until several months later. In the meantime the building occupied by the government laboratories has become too cramped by reason of the constantly increasing volume of work which is carried on, and the biological division has been crowded out and forced to take up temporary quarters in a rented building on Calle Iris, pending the completion of the new laboratory building.

PAIL CONSERVANCY SYSTEM. — Major G. M. Barber has just been appointed to a position under the Board of Health in charge of the operation of the pail conservancy system for the disposal of excreta and of the work of scavenging and removal of refuse. Major Barber has been connected with the street-cleaning departments of New York and Chicago, and comes directly from Cuba, where, under the direction of General Wood, he accomplished the cleaning up of the city of Santiago, and brought its street-clean-

ing and scavenging force up to a high state of efficiency. His experience should make him a valuable man for similar work in Manila, though local conditions are even less favorable here than they were in Santiago.

Removal of Board of Health Offices. — The Board of Health has lately moved its offices from the Ayuntamiento to more commodious quarters in the Potenciana building, where it will be permanently established.

Appointment of Police Surgeon of Manila. — Dr. Albert T. Short, until lately a contract surgeon in the army, has recently been appointed police surgeon of Manila. He is one of several American physicians who have married into Filipino families, and expects to remain in the islands permanently. As the police force is composed of both Americans and Filipinos, Dr. Short's appointment will probably be agreeable to all concerned.

Leper Colony. — Work on the leper colony at Kulion has been abandoned for the rainy season. The work has been much delayed by the absolute impossibility of securing laborers from among the Filipinos. Progress here along all lines is much hampered from this cause. With the rigid exclusion of Chinese enforced, the manual labor proposition resolves itself into the fact that the white man cannot work, the Filipino won't and the Chinaman is not allowed to do so.

"Rinderpest Meat." — A committee has been appointed to investigate and report upon the use as food of meat from animals affected with rinderpest. The board found that such meat has habitually been used by the natives without apparent ill effects, and that although the use of flesh from any sick animal was undesirable, meat from rinderpest animals could not be regarded as directly injurious to health. In view of this fact, and considering the question of the effect of such prohibition upon the price of meat, the board recommended that the sale of meat from rinderpest animals be for the present authorized, provided these animals be in the early stages of the disease, the meat be stamped "rinderpest meat" and be sold only by authorized dealers placing placards in their stores stating that they dealt in such meat.

Improvement in Cholera Situation. — In view of the recent great diminution in the number of cholera cases, and the fact that those which occur are largely traceable to the use of infected water from the Pasig River, the health authorities have lately felt justified in largely modifying the prohibited food list which has been in force for nearly a year. Pineapples, guavas and fruits which are peeled before being eaten are now allowed. The restrictions still remain in force as regards salad vegetables, molluscs and certain prepared articles of food used by the Chinese and natives. So far, this relaxation in the precautions relative to the foods allowed to be sold does not seem to have had any harmful results.

Correspondence.

BRADYCARDIA.

Boston, Sept. 12, 1903.

Mr. Editor: I am pleased to read among the journals of late, an awakened interest in bradycardia, about the pathology of which we seem to have a great deal to learn. The difficulty for the general practitioner is a real one so far as treatment is concerned, at least at the present time. I have had a patient with this condition of slow pulse under my care, off and on, for two years. The patient is a man of sixty-seven years, with a pulse of 24, regular, of medium tension; he was never sick in his life, as he says, but for the past year the sight leaves his eyes momentarily, and he has learned the trick of standing as erect as possible, making his spine rigid to find relief — "in a minute 'tis all gone."

He has a burning feeling over his heart — by this he means in the skin, "nothing to do with the stomach." This "burning" only exists when he is working, his occupation being street cleaning, and he imagines the whole side is coming out at this part. At times he falls forward, as the scars on his head testify, and just as soon as he strikes the ground, he gets right up again and recovers his "senses." It must not be inferred from his use of the word "senses" that he loses consciousness. What he means is "that the blood stops" in his head. He cannot lie on his left side, for he has a feeling of oppressive "weight on his heart." He cannot stoop down without being dizzy. His brachial arteries are tortuous, locomotive, and may be well called pipe-stem arteries; these are the only arteries that are so affected. The cardiac apex impulse is in the sixth interspace, a finger's breadth outside the nipple line. On light percussion cardiac dullness does not begin until the fourth costal cartilage is reached. The right border of the heart is apparently at the mid-sternal line. He feels perfectly well but for this burning over his heart and these attacks of falling and the sight leaving his eyes momentarily, as above mentioned. I stopped his work for a while, and put him on iodide of potash, which gave him relief for a time, but its good effects did not continue. I made a very careful examination again, and then found a slight edema of both ankles scarcely observable to the man himself, but there it was unmistakably. I put him on digitalis, moderate doses, and cautiously, with much benefit. The man said his feet never swelled until he stopped work, or he never noticed if they did. This may be so. I think idleness would not benefit him as much as moderate work, and I have advised him to seek such, and abandon the more laborious street cleaning. If I had not sought carefully and found the slight edema above mentioned, I would be at a loss to know what medicinal treatment of such a case should be given. The digitalis helps my patient, and he is taking it cautiously right along. The description "*Pouls lent permanent avec attaques syncopales et epileptiformes*" applies to this man's case very nicely.

John J. Hanley, M.D., M.R.C.S. (Eng.)

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, SEPT. 5, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 1,419; under five years of age, 480; principal infectious diseases (smallpox, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 503, acute lung diseases 87, consumption 136, scarlet fever 6, whooping cough 10, cerebrospinal meningitis 6, smallpox 15, erysipelas 1, measles 4, typhoid fever 52, diarrheal diseases 243, diphtheria and croup 27.

From whooping cough, Baltimore 1, Pittsburg 2, Boston 3, Salem 1, Newton 2, Westfield 1. From erysipelas, Pittsburg 1. From measles Chicago 1, Pittsburg 1, Providence 2. From smallpox, Pittsburg 15.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Aug. 22 the death-rate was 15.7. Deaths reported, 4,548; acute diseases of the respiratory organs (London) 120, whooping cough 54, diphtheria 35, measles 84, smallpox 2, scarlet fever 36.

The death-rate ranged from 4.0 in Hornsey to 32.6 in Bootle; London 14.4, West Ham 14.1, Brighton 12.9, Portsmouth 15.2, Southampton 18.5, Plymouth 16.8, Bristol 11.7, Birmingham 16.4, Leicester 14.0, Nottingham 19.3, Bolton 22.6, Manchester 19.5, Salford 20.3, Bradford 15.5, Leeds 15.8, Hull 21.3, Newcastle-on-Tyne 21.8, Cardiff 13.0, Rhondda 13.9, Liverpool 22.1, Reading 6.9, Bootle 13.7.

METEOROLOGICAL RECORD.

SOCIETY NOTICE.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The thirty-first annual meeting of the American Public Health Association will be held at Washington, D. C., beginning Oct. 26 and continuing for five days.

THE PRIZE ESSAY OF THE AMERICAN MEDICAL ASSOCIATION.

THE AMERICAN MEDICAL ASSOCIATION offers annually a gold medal, value of $100, for the best essay on any subject relating to medicine or surgery. The recipient of this prize will be given the option of the gold medal, or a bronze replica of the medal and the balance of the appropriation (about $90) in money, or the entire amount ($100) in money.

Inasmuch as the Association annually sets apart the sum of $500 for original research, this prize is offered to stimulate the production of a superior practical paper, based either upon experimental studies or clinical investigation, or both. The committee will give preference to papers having the greatest brevity consistent with thorough consideration of the subject, and recommends that the paper shall not exceed 5,000 words. The committee, while not restricting the choice of subjects, recommends as an important subject for consideration, "The Therapeutic Value of the Digestive Ferments."

Competing essays must be typewritten, and bear no mark revealing their authorship; but instead of the name of the author there must appear on each essay a motto, and accompanying each essay a sealed envelope containing the name of the author and bearing on its outer surface the motto of identification. No envelope will be opened by the committee until a decision has been reached as to the most deserving essay. The other essays will be returned to their respective authors. The committee reserves the right to reject all essays if none are found worthy of the Association medal. Competing essays must be in the hands of the chairman of the committee not later than April 1, 1904.

LEWIS S. MCMURTRY, Louisville, Ky., Chairman.
BURNSIDE FOSTER, St. Paul, Minn.
M. H. FUSSELL, Philadelphia, Pa.

Committee.

RECENT DEATHS.

LUIS P. WALTON, M.D., a well-known New York physician, died suddenly of cardiac disease at the Bath Club, London, on Sept. 8. He was graduated from the College of Physicians and Surgeons, New York, in 1870. He was an Englishman by birth, and was buried at Kensal Green Cemetery on Sept. 14.

NORTON FOLSOM, M.D., M.M.S.S., died in Cambridge, Sept. 12, 1903, aged sixty-one years.

JOSEPH PEARSON OLIVER, M.D., M.M.S.S., of Boston, died in Paris, France, Sept. 11, 1903.

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book of the Diseases of Women. By Thomas A. Ashby, M.D. Illustrated. Baltimore: Williams & Wilkins Company. 1903.

THE ILL HEALTH OF FRANCIS PARKMAN.

BY GEORGE M. GOULD, M.D., PHILADELPHIA, PA.

(Continued from No. 12, p. 309.)

Farnham writes as follows:

He passed through at least four severe crises of pain and disability within a period of twenty years. The extent of his sufferings is nowhere revealed, only hinted at in writing; he is remembered, however, by an intimate friend or two to have said that death would often have been a welcome end of his trials. Generally he passed acute attacks either in turning his thoughts and conversation to light and jocose topics, or in silent and patient endurance. Once, when his physican, during a bad attack, encouraged him by saying that he had a strong constitution, Parkman replied quaintly, "I'm afraid I have." There is nothing to tell of these crises beyond the patience and fortitude with which he endured them. Sometimes, however, he felt so strongly that he had had more than his share of suffering, that a fresh attack would cause him to explode in a few very forcible expressions; then his quiet patience soon regained the mastery.

Parkman has said:

From a complete and ample experience of both, I can bear witness that no amount of physical pain is so intolerable as the position of being stranded and doomed to lie rotting for year after year. However, I have not yet abandoned any plan which I ever formed, and I have no intention of abandoning any.[8]

Driven to horticulture. — With a productive ability limited to about six lines a day, and the use of "the gridiron" to do so much, even Parkman's stout heart was daunted. But he met fate most courageously, and the manner of doing it again shows plainly the lesson to be found in his previous experiences. That he was not an eager and spontaneous nature-lover is clear from the fact that the woods were left by him unvisited for forty years after that phase of the reaction had passed in his youth.[9] That he cared nothing for chemistry comes out in the fact that he never busied himself with it a minute after the enthusiasm of his boyhood had passed. That travel and journeys among Indians, etc., in search of materials for his histories was not demanded by the historical mind is again manifest that the "Oregon Trail" had exhausted that necessity. All these, his rage for athletics and similar facts, demonstrate that these methods of spending energy served the sole purpose of satisfying the demands of his nervous mechanism for an outlet for derouted energy. They were caught up compromises with the compelling demon, who denied legitimate and logical obedience, forced the boy and the man to a morbid and excessive activity in any way that circumstance pointed. But at every step in life there was the growing impossibility of carrying out the ideal, even by the most abnormal energies or the most pathetic self-renunciation. Only the tragedy of Carlyle's similar life and experience can be compared with that of Parkman, and in exquisite poignancy Parkman's seems the more awful. Just as all previous attempts to meet the ingravescent evil had been morbid methods of disposing of the energy of the reflex ocular neurosis, which was his abiding source of mischief, so now Parkman was compelled to turn his attention to horticulture. From 1851 to 1865 there was published no considerable work; a novel and a book of verses gave glimpses only of the imprisoned soul crying out in the night. His sister tells me that during these years not all preparations for historical work were renounced. Something was always going on, at least in his mind.

His biographer says of him that as to his health he showed a commendable docility when advised by his physicians, but that "in one particular he persistently refused obedience — he would not give up his literary labor wholly, even when the doctors forbade it under threats of the most serious consequences; and when they told him to prepare for death, he straightway prepared to write books." At last, however, driven entirely to the wall, being unable to use his eyes even to sign his name, he adopted horticulture as an outlet for his energy and to fill the time with some occupation as close to his hand and as interesting as possible.

When able to walk he would go at a rapid gait from place to place, and sit down on a stool carried for the purpose; he would then do some of the lighter work, such as sowing seeds, planting borders, weeding and cultivating. . . . Sometimes the sensitiveness of his eyes prevented him from being out of doors in the sunlight. He acquired great fame as a horticulturist.

There are abundant evidences that he was not profoundly interested in this subject, and all his botanical successes and fame did not keep his mind's eye from the one aim of his life to which he returned so soon as his eyes and health permitted.

Fighting it out with "the enemy." — Parkman was accustomed to anthropomorphize the hidden sources of his physiologic evils as "the enemy" or his "cerebral devil." He had no mind to be defeated in the battle, and least of all to acknowledge defeat. Lamed though he was, his brisk step and alert manner made a French friend call him by the nickname of the *cerf agile*. "He could never abide weakness," says Farnham, "either physical, mental or moral; men, women, opinions, emotions, to command his admiration must show strength and energy." "Even when confined to his wheelchair he would split wood, hoe in the garden, rake or cut grass,

[8] Farnham was doubtless justified in quoting as having a personal significance and application a passage from Parkman's novel:

"It is but a weak punishment to which Milton dooms his ruined angel. Action, enterprise, achievement, — a hell like that is heaven to the cells of Ehrenberg. He should have chained him to a rock and left him alone to the torture of his own thoughts; the unutterable agonies of a mind preying on itself for want of other sustenance. Action! mured in this dungeon, the soul gasps for it as the lungs for air. Action, action, action! — all in all! What is life without it? A marsh, a quagmire, a rotten, stagnant pool. It is its own reward. The chase is all; the prize nothing."

And how personal are his reflections on the prospect of no escape from his misfortunes:

"Yet it is something that I can still find heart to face my doom; that there are still moments when I dare to meet this death-in-life, this slow-consuming horror, face to face, and look into all its hideousness without shrinking. To creep on to my end through years of slow decay, mind and soul famishing in solitude, sapped and worn, eaten and fretted away, by the droppings of lonely thought till I find my rest at last under these cursed stones."

[9] It is surprising that he should never once have sought the wilderness during forty years after his trip to the Rocky Mountains. His lameness naturally made travel in the woods difficult; yet he often journeyed far to collect historic material. But it is probable that he loved the adventures of a wild life more than the wilderness itself; and therefore neither the woods nor the prairies had of themselves power to attract him after his infirmities denied him perfect freedom in physical activity. Certainly he drove on his literary labors in spite of obstacles, with a persistence, courage and energy that would have enabled him frequently to visit the wilderness had the love of nature been his dominant passion.

etc." "One day in talking over a biographical notice in which a friend had dwelt on the historian's feebleness, he exclaimed, 'Damn it, I'm not feeble!'"

Shortly after the death of his wife he went abroad, and spent the winter of 1858–59 in Paris, at the Hôtel de France et de Bath. His brain was then in such a condition that the most eminent specialists of Paris warned him against insanity and forbade him all literary labor; but while spending his time chiefly in observing the life of the streets from the tops of omnibuses, he yet managed to make some investigations in the archives and to arrange for the copying of documents. Returning to Boston without any improvement in his alarming condition, he joined the family of his mother and sisters.

1868 was a year of exceptional suffering, rendering all work impossible, although he accepted election as overseer of Harvard College. Finding that complete idleness now seemed necessary, and preferring Paris to any other place for such a life, he went abroad for the winter, establishing himself in lodgings at No. 21 Boulevard Saint Michel. Here he was vainly sought after by some of the writers of Paris and the élite of the Faubourg St. Germain. In the course of the winter his health improved sufficiently to enable him to enjoy sightseeing and even make some researches, so that at his return in the spring of 1869 he resumed his labors and saw "La Salle" through the press.

In 1886 he camped a month with me. . . . His lame knee. . . . He could not walk enough to do more than fire a few rounds in camp at a target. . . . His infirmities never allowed him to make the journey a second time.

His maladies compelled him in 1888 to resign his office of Fellow of the Corporation of Harvard after a service of thirteen years.

The close of Parkman's life was both happy and characteristic: his work done, his reputation still in the ascendant, his friends increasing in number and appreciation. He had always hoped to die before reaching the lingering weakness and decrepitude of old age, for such a soul could not but dread anything that even pointed towards a diminution of power. When a friend once spoke with pride of the work he had done, his energy flamed out with the promise to do still more if he should live. His last summer was a very happy one; comparative freedom from pain and the absence of anxiety as to the completion of his work brought both comfort and peace.

He had phlebitis of the leg in 1892, and for the first time he was then compelled to take to his bed.

On coming in from his last row, on a Sunday, he felt ill and took to his bed. Peritonitis set in, but he rallied so much by Tuesday evening that a successful surgical operation was thought possible. This hope had to be dismissed when he began to sink on Wednesday morning. He died peacefully about noon of that day, on the 8th of November, 1893.

Parkman's method of carrying on literary work. — The following quotations seem necessary to give the student of this case an adequate sense of the difficulties and cost of Parkman's ocular abnormality. They are from the autobiography:

He then entered upon the subject of "France in the New World," a work, or series of works, involving minute and extended investigation. The difficulties which met him at the outset were incalculable. Wholly unable to use his eyes, he had before him the task, irksome at best when there is no natural inclination for it, of tracing out, collecting, indexing, arranging and digesting a great mass of incongruous material scattered on both sides of the Atlantic. Those pursuing historical studies under the disadvantages of impaired sight have not hitherto attempted in person this kind of work during the period of their disability, but have deputed it to skilled and trusty assistants, a most wise course in cases where it is practicable. The writer, however, partly from the nature of his subject and his plan, though in special instances receiving very valuable aid, was forced in the main to rely on his own research. The language was chiefly French, and the reader was a girl from the public schools, ignorant of any tongue but her own. The effect, though highly amusing to bystanders, was far from being so to the person endeavoring to follow the meaning of this singular jargon. Catalogues, indexes, tables of contents in abundance were, however, read, and correspondence opened with those who could lend aid or information. Good progress had been made in the preliminary surveys, and many books examined and digested on a systematic plan for future reference, when a disaster befell the writer which set his calculations at naught.

This was an effusion of water on the left knee.

In the severer periods of the disorder, books were discarded for horticulture, which benign pursuit has proved most salutary in its influences. One year, four years and numerous short intervals, lasting from a day to a month, represent these literary interruptions since the work in hand was begun. Under the most favorable conditions, it was a slow and doubtful navigation, beset with reefs and breakers, demanding a constant lookout and a constant throwing of the lead. Of late years, however, the condition of the sight has so far improved as to permit reading, not exceeding, on the average, five minutes at one time. This modicum of power, though apparently trifling, proved of the greatest service, since, by a cautious management, its application may be extended. By reading for one minute, and then resting for an equal time, this alternate process may generally be continued for about half an hour. Then, after a sufficient interval, it may be repeated, often three or four times in the course of the day. By this means nearly the whole of the volume now offered has been composed. When the conditions were such as to render systematic application possible, a reader has been employed, usually a pupil of the public schools. On one occasion, however, the services of a young man, highly intelligent, and an excellent linguist, were obtained for a short time. With such assistance every difficulty vanished, but it could not long be continued.

How far, by a process combining the slowness of the tortoise with the uncertainty of the hare, an undertaking of close and extended research can be advanced, is a question to solve which there is no aid from precedent, since it does not appear that an attempt under similar circumstances has hitherto been made. The writer looks, however, for a fair degree of success.

In the second letter he said: "While engaged on these books, I made many journeys in the United States and Canada in search of material, and went four times to Europe with a similar object. The task of exploring archives and collecting documents, to me repulsive at the best, was under the circumstances difficult, and would have been impossible but for the aid of competent assistants working under my direction."

In writing his second letter he said: "Taking the last forty years as a whole, the capacity of literary work which during that time has fallen to my share has, I am confident, been considerably less than a fourth part of what it would have been under normal conditions."

Farnham adds:

In looking at the great mass of manuscript he collected and digested, one partially realizes by the material evidence of mere bulk how much he did for the sake of thoroughness, but fully only when one remembers the weakness of eyes and brain that increased his labors tenfold. In the preface to "A Half Century of Conflict" he thus referred to his collection at the close of his labors:

"The manuscript material, collected for the preparation of the series now complete, forms about seventy volumes, most of them folios. These have been given by me from time to time to the Massachusetts Historical Society, in whose library they now are open to the examination of those interested in the subjects of which they treat. The collection was begun forty-five years ago, and its formation has been exceedingly slow, having been retarded by difficulties which seemed insurmountable, and for years were so in fact. Hence the completion of the series has required twice the time that would have sufficed under less unfavorable conditions."

While he was in the Law School his sister Miss Eliza S. Parkman remembers that he was ill in bed, and that she began at this time reading to him. She does not know of what he ailed at that time. She was his helper in his literary labors for much of the remainder of his life. Whenever he was able to do any such work it was usually as follows: He made his notes, if able to do so, in the method stated, by writing for a minute or two and then stopping to look at a distance to rest his eyes. He prepared for his dictation by thinking, and usually while lying on his back upon a lounge. He went to his room at nine o'clock in the morning, and if he could dictate for an hour it was considered a good day's work. He could not generally continue so long, a half-hour in the forenoon and less in the afternoon being all he could get through with. He usually held a screen before his eyes while dictating. At first he used no notes while dictating, but later he constantly consulted them. He could only read at best but a few minutes, generally but one or two, and he never did any reading or writing whatever at night. He habitually avoided looking at any one or at any object steadily. In any sort of literary work, or even while being read to, he would often have to stop with the remark that his head was all "stirred up." A continuous noise tormented him and quiet was always desired. His power to read or write seemed to depend upon his eyes rather than upon his head.

Parkman's estimate of his own case. — It is evident that the mystery of his own ailment weighed so deeply upon his mind that it gave him the strong incentive needed to break over his natural reserve and disinclination to speak of himself. This mystery, he felt, must some time be solved, and the autobiographic letter was his attempt to hand to some aftercomer a document giving so far as in him lay the facts of his strange disease. It must be remembered that it was written in 1868, just prior to his going abroad for medical advice and historical research. It was sealed and inscribed as "not to be used during my life." These are the opening sentences:

> Allusion was made at the outset to obstacles which have checked the progress of the work, if the name of obstacles can be applied to obstructions at times impassable and of such a nature that even to contend against them would have been little else than an act of self-destruction. The case in question is certainly an exceptional one; but as it has analogies with various other cases, not rare under the stimulus of our social and material influences, a knowledge of it may prove of use. For this, as for other reasons, the writer judges it expedient to state it in full, though in doing so much personal detail must needs be involved.

In the introductory note he had said:

> It resulted from a desire — natural perhaps, but which may just as well be suppressed — to make known the extreme difficulties which have reduced to very small proportions what might otherwise have been a good measure of achievement. Having once begun it, I went on with it, though convinced that it was wholly unsuited to see the light. Physiologically considered, the case is rather curious. My plan of life from the first was such as would have secured great bodily vigor in nineteen cases out of twenty, and was only defeated in its aim by an inborn irritability of constitution which required gentler treatment than I gave it. If I had my life to live over again, I would follow exactly the same course again, only with less vehemence.

In this recognition of "an inborn irritability of constitution" which defeated his life purpose, Parkman puts his finger, or rather points it, to the heart of the mystery. Again the same inerrant perception appears in his words:

> It was impossible that conditions of the nervous system, abnormal as his had been from infancy, should be without their effects on the mind, and some of these were of a nature highly to exasperate him. Unconscious of their character and origin, etc.
>
> . . . . . .
>
> Though the seat of derangement may be the nervous system, it does not of necessity follow that the subject is that which, in the common sense of the word, is called "nervous." The writer was now and then felicitated on "having no nerves" by those who thought themselves maltreated by that mysterious portion of human organism. This subterranean character of the mischief, early declaring itself at the surface, doubtless increased its intensity while it saved it from being a nuisance to those around.

None to whom was hidden the truth of the cerebral and psychic effects of great eyestrain could more accurately describe the tormenting mystery of his case than Parkman has done in the foregoing citations. By this time in his life he was able to see the folly of his athleticism and especially of the "Oregon Trail" to overcome "the enemy," concerning which he now wrote:

> As to the advantages of this method of dealing with that subtle personage, some question may have arisen in his mind, when, returning after a few months to the settlements, he found himself but ill adapted to support his theory.

In 1851 he was confined for two years by "an effusion of water on the left knee." And Parkman adds:

> The effects of the confinement were as curious as unenviable. All the irritability of the system centered in the head. The most definite of the effects produced was one closely resembling the tension of an iron band, secured around the head and contracting with an extreme force, with the attempt to concentrate the thoughts, listen to reading or at times to engage in conversation. This was, however, endurable in comparison with other forms of attack, which cannot be intelligibly described from want of analogous sensations by which to convey the requisite impressions. The brain was stimulated to a restless activity impelling through it a headlong current of thought, which, however, must be arrested and the irritated organ held in quiescence on a penalty to avert which no degree of exertion was too costly. The whirl, the confusion and strange, undefined torture attending this condition are only to be conceived by one who has felt them. Possibly they may have analogies in the savage punishment once in use in some of our prisons, where drops of water were made to fall from a height on the shaved head of the offender, soon producing an effect which brought to reason the most contumacious. Sleep, of course, was banished during the periods of attack, and in its place was demanded, for the exclusion of thought, an effort more severe than the writer has ever put forth in any other cause. In a few hours, however, a condition of exhaustion would ensue; and, both patient and disease being spent, the latter fell into a dull lethargic stage far more supportable. Excitement or alarm would probably have proved wholly ruinous.

This account is so incomparably accurate and descriptive of the cerebral effects of severe eyestrain that it may be incorporated in textbooks. Innumerable patients have perhaps less exactly but with the same intent and vehemence, and in similar terms, described their symptoms to their

oculists. The "iron band about the head," the vague but intolerable anguish, the "whirl," the "confusion," the "strange, undefined torture," "all the irritability of the system centered in the head" — such are precisely the expressions used by these sufferers. And these symptoms disappear with proper glasses.

The so-called heart trouble. — In 1844 Parkman referred to "a painful beating of his heart." Farnham says that some thought his sudden journey to Europe in 1844 on account of ill health was a trouble of the heart resulting from overstrain in the gymnasium at Harvard. Parkman in his diary, in 1844, speaks of the "cursed injury that brought me to Europe," adding, "as I find no great improvement, I judge it best to see what a French doctor can do for me, instead of running about Spain."

Farnham adds:

> This affection, however, does not seem to have been a persistent trouble; it did not prevent him, even at that time, from walking, climbing mountains and ascending cathedral spires as only a vigorous man can do; and the malady does not figure among the chronic troubles of his after life. There is no subsequent mention in his diaries either of disease or medical treatment.

The matter is of no medical importance except to note that, as with several of the other cases studied, this patient also had for a time his cardiac worry.

Rheumatism and lameness. — The arthritis of the knee came on in 1851, and for two years he was unable to walk much. In 1852 he had to be carried out of the house when starting on his trip to the water cure establishment in Northampton, Mass. For many years his lameness did not prevent free walking at times nor horseback exercise; he used also to do what digging and other work he could in his garden. Fortunately his arms remained serviceable till very near the close of his life, so that he could generally enjoy some form of exercise with them. Even when confined to his wheelchair he could split wood, hoe in his garden, rake or cut with a sickle the grass along the walks; he even did some carpenter work in making foot benches or other objects of utility. During much of his later years he was obliged to use canes or crutches and to carry a stool when working in his garden. Disliking eccentricity of all kinds, he was much annoyed at having to walk in the streets in his peculiar manner; yet he would not give up exercise or social intercourse so long as he could enjoy them by any means whatever. The pain and the loss of freedom caused by his lameness led him for a time to consider amputation of the leg; but the relief hoped for was too doubtful to justify the operation. When rheumatism finally came in the shoulders and stopped the last of his out-of-door exercises, he accepted massage, practiced deep breathing and such other movements as could be executed in a chair.

Wheelwright says of his lameness in his later years:

> Long years afterward, when crippled by disease and needing two canes to support his step, he might often be seen in the streets of Boston, walking rapidly for a short distance, then suddenly stopping, wheeling around and propping himself against the wall of a house to give a moment's repose to his enfeebled knee. Whatever he did, he must do it with all his might. He could not saunter, he could not creep; he must move rapidly or stand still. On these walks in the country he often carried his rifle, "Satan." He also did some rowing on Fresh Pond.

Even when his life work was practically over, when completed presbyopia allowed him to enjoy more reading and an untortured brain, the fates would still not relent. There was an exacerbation of the knee trouble, and this, keeping him from exercise, led to an increase of insomnia, etc.[10]

During the last years of his life his lameness was so troublesome that he had an elevator in his house which he was able to operate by his own arms, and in this way he went up stairs and down. This intercurrent affection has of course no significance as regards the disease-producing ocular condition, except that it confined him more, and thus increased his tendency to read or write, which at once resulted in a heightening of his cerebral and nervous reflexes.

Parkman's insanity. — The collocation of the words "Parkman" and "insanity" arouses a scornful smile. Insanity was as impossible to that splendid and sound mental and cerebral mechanism as to any in the world. The best proof is that the awful irritation, insult, injury and strain which it endured did not cause it to swerve from its perfect poise and self-control for a minute. And yet the absurd suspicion was entertained by some, and with the thought Parkman was forced to play. He never seriously believed in the theory, but he could play with it as only an eminently sane mind can with such things. Like all eyestrain sufferers, like those especially we have studied, Parkman had the greatest need, physically, mentally and particularly ocularly, of much out-of-door life and exercise. The irritable reflexes from the eyes were always surcharging the battery of his brain,

[10] For illustration of this period I cannot forbear quoting a letter kindly given me by Dr. Oliver. It is as follows:

SARAGOSSA, SPAIN, 14 April, 1887.

My dear Dr. Oliver, — Excuse the pencil scrawl. Persistent sleeplessness and the fatigue of travel on the damned Spanish trains, which go chiefly by night, has made my head too shaky for a pen. Since landing I have slept, when stationary, from two to four hours, with two favorable exceptions of five or six hours each (helped by chloral and bromide). I am sorry not to report more brilliant results. I should hope, however, for better luck were it not that the old lameness in my left knee — the result of water on the knee thirty-six years ago — has mysteriously returned after leaving me tolerably in peace for more than twenty years. The consequence is that I cannot walk above a few moments at a time without pain. Sometimes I can scarcely walk at all. This has lasted eight or nine days, and, though it fluctuates a good deal, it has not yet improved. Hence my plans are upset. As I lose ground here, and as traveling by rail is excessively difficult under the circumstances, I have beguiled Coolidge — who is the most disinterested of men — into making a straight course for the Mediterranean coast. We hope to find a steamer at Barcelona to carry us to Gibraltar, whence, if things improve with me, we will go together to Grenada, etc. But if the lameness continues, I see no use whatever in remaining on this side of the water. Therefore, unless there is perceptible improvement, I shall probably take a steamer at Gibraltar either directly for New York or indirectly by Southampton.

Yours very truly,
F. PARKMAN.

Postscript:

BARCELONA, 17 April.

Change of plan. No available steamer here for Gibraltar. Lameness rather worse. Mean to start for Paris by day train. When there if lameness is in a better way than now, I mean to go at once to Schlangenbad. If on the other hand it shows no signs of improvement, I shall take passage for Boston, since living alone at Schlangenbad with no possibility of exercise cannot conduce to health. This cursed lameness is a thing which neither you nor I could foresee and which changes the whole situation. Yours, F. P.

which, chronically in a state of overtension, needed the physical exercise and the ocular rest. His captivity from lameness must have been grievous to bear, and he sought compensation for it in many ways. There is another reason why his lameness must have greatly embittered his mind, although he alludes to it but once. When the war broke out in 1861, what suffering it must have caused him that he could not join the army! What a general he would have made!

This virtue (cheerfulness) had exceptional value in his case, because of his *inherited affection* of the brain; and he was fortunate in early coming to the belief that insanity often begins in moods and mental conditions that at the beginning can be avoided. (Farnham.)
